* The present exchange value of the rupee is about 1s. 10½d.
S.L. = Selected List.

Charge allowances and second-in-command allowances for station hospitals will be admissible in addition to the above rates of pay at the following rates :—

(a) Charge Allowance.		(b) Second-in-Command Allowance.	
	Rs. per mensem.		Rs. per mensem.
1st class hospitals ...	240	1st class hospitals ...	120
2nd class hospitals ...	180	2nd class hospitals ...	90
3rd class hospitals ...	120		
4th and 5th class hospitals	nil.		

All existing general allowances paid to holders of professional and bacteriological appointments and certain other special classes of appointments on the civil side to be maintained.

Indian officers who have joined or may join the Service after Dec. 1st, 1918, will draw, as from Jan. 1st, 1920, pay in accordance with the basic scale set forth below, unless they are already drawing pay at a higher rate, in which case they will continue to enjoy the benefit of that rate for so long as they would otherwise have done; but they will not receive any further increment until it is due to them under the basic scale.

PENSIONS.

The pension rates as now revised give £400 a year after 17 years' service, increasing to £800 after 27 years' service. Formerly the rate was £300 after 17 years' service, increasing to £700 after 30 years' service.

Pension Rates.

After 17 years' service	£400	After 23 years' service	£620
" 18 "	430	" 24 "	660
" 19 "	460	" 25 "	700
" 20 "	500	" 26 "	750
" 21 "	540	" 27 "	800
" 22 "	580		

Additional pensions for administrative officers :—

Colonel, after two years' active service as such	£125
After four years	250
Major-General, after one and a half years' active service as such	300
After three years	350

It is quite impossible to foretell how and to what extent the civil side of the I.M.S. will be affected by the Indian Reform scheme now about to be introduced. The Act does not touch in any way on the military side of the Service. The essence of the reform is in the increasing participation of Indians in the government of the country, and consequently we consider it right to draw the attention of young medical men who are considering joining the Indian Medical Service to this aspect. At the same time we see no reason why the increased co-operation of Indian and European medical officers should not, if a sympathetic attitude is adopted, result in the benefit of both. The number of Indians in the I.M.S. in the days of the competitive examination varied from 8 to 12 per cent. In the two or three years before the war the percentage of successful Indian candidates varied from 12 to 30 per cent. At the present time European and Indian candidates are admitted by nomination in the proportion of 2 Europeans to 1 Indian. A strict system of selection is maintained and permanent commissions are only granted to candidates, whether Europeans or Indians, who have been recommended after a personal interview as suitable and desirable professionally and socially. Practically all the Indian candidates recommended so far have served in the field with distinction and have been recommended by two of their brother officers for the grant of a permanent commission.

A Board of Selection has been appointed in India for the recruitment of permanent officers for the I.M.S. in the manner indicated, consisting of the Director-General, I.M.S., the Director of Medical Services in India, and an Indian Officer, I.M.S. Candidates who may be summoned by the Board for interview will, if considered suitable for appointment, be placed in one of two classes, according as they have or have not received their medical education chiefly in Great Britain. The final recommendations as to the former will be made by the Selection Board in England, while the recommendations as to the latter will be sent direct from India to the Secretary of State, who will make appointments to fill the vacancies. The Selection Committee in England, in addition to considering applications from India of candidates who have mainly received their education in England, will review those of the candidates in the United Kingdom; but not the recommendations of the Indian Committee in regard to candidates educated in that country.

Temporary Commissions.—To meet the present shortage in the cadre of the I.M.S. a special contract is provided for the grant of temporary commissions to European medical officers. The terms of this contract are well worth the consideration of those practitioners who, for private reasons, do not wish to make a definite decision for permanent service in India.

A temporary commission is granted for two years with pay at Rs. 700 per mensem for lieutenants and Rs. 750 for captains. Three years' service as a medical officer with the Home, Colonial, or Indian forces qualify for the higher rate.

A first-class passage to and from India is granted, and a £50 outfit allowance. Leave is granted under ordinary military rules, and if an officer has not been able to take one month's privilege leave for each year of service he may get the balance at the expiration of his term of engagement. Applicants who, at the end of the period of temporary service apply, and, being eligible, are accepted for permanent commissions in the I.M.S., will be allowed to count their temporary service for rank, gratuity, and pension. Under such a contract any young medical officer has a splendid opportunity of seeing the world under very favourable conditions and determining on the spot whether it is to his advantage or otherwise to continue serving in the East as a permanent officer of the Indian Medical Service.

For full particulars intending candidates should apply to the Secretary, Military Department, India Office, Whitehall, London, S.W. 1.

AIR FORCE MEDICAL SERVICE.

THE Royal Air Force Medical Service is now definitely established, and, except for a few points which are still under consideration, the conditions of service have received the sanction of His Majesty's Government. This new Service offers a career for medical men which should prove both attractive and interesting. The rates of pay and allowances are good, and a new field of scientific interest is opened up by the manifold problems which the circumstances of aviation produce. The physical and mental fitness for, and reaction to, the varied conditions under which the flying personnel perform their functions provide much scope for research. As promotion to the higher ranks of the Service is to be entirely by selection, and as a certain proportion of the higher ranks will be reserved for purely scientific, as opposed to administrative, appointments, it will be seen that there are excellent prospects for the young medical officer who exhibits ability and energy in scientific research, as well as for those who develop a talent for administration.

The establishment will consist partly of permanent and partly of short-service officers. Short-service officers will be admitted by direct entry for a period of two years, which may be extended to four years at the discretion of the Air Council on recommendation of the Director of Medical Services. Those who are not selected for permanent commissions will pass into the Royal Air Force Medical Reserve at the expiration of their period of service on the active list, and will then receive gratuity to which their service entitles them.

Short-service officers who are approved for permanent commissions, but for whom there are not vacancies in the Royal Air Force Medical Service, may, under certain conditions, transfer to the Royal Army Medical Corps, counting their time served in the Royal Air Force towards increments of pay and retired pay in the Royal Army Medical Corps. Arrangements are being made to allow post-graduate courses after selection for permanent commission.

New entrants into the Royal Air Force Medical Service will be commissioned as Flying Officers (Medical) and will be eligible for promotion to the rank of Flight Lieutenant (Medical) after two years' service. Officers selected for permanent commissions will be promoted to the rank of Squadron Leader after 10 years' total service. Accelerated promotion may be carried out, in a limited number of cases, of officers who show exceptional ability after the completion of eight years' service. Promotion to the rank of Wing Commander will be by selection at any period after 16 years' total service, and to that of Group Captain by selection at any period after 22 years' service.

There will be no competitive examination on entry; candidates must be under 28 years of age, be nominated by the Dean of a recognised medical school or teaching hospital, and will be interviewed personally by the Director of Medical Services, Royal Air Force, before acceptance. Each candidate must produce—

1. Birth certificate.
2. Medical registration certificate.
3. A declaration containing the following information:—

- (a) Age and place of birth.
- (b) That he is of pure European descent, and the son of a subject of the British Empire.
- (c) That he labours under no constitutional or mental disease or disability which may interfere with the efficient discharge of the duties of a medical officer in any climate in peace or war. (All candidates will be required to pass a medical examination as to their physical fitness before acceptance to ensure that they fulfil the standard laid down in this declaration.)
- (d) That he is ready to engage for general service at home or abroad as required.
- (e) The qualifications he is possessed of, and what medical or other appointments he has held (if any).
- (f) That he is willing to fly whenever called upon to do so, and to qualify in such aviation tests as may be required.

If the applicant is in possession of a certificate of training in an Officers' Training Corps this should be submitted.

An applicant who at the time of application holds or is about to hold, a resident appointment in a recognised civil hospital may be seconded for the period not exceeding one year, during which he holds such appointment. Whilst seconded he will not receive pay from Air Council funds, but

his seniority will count from the day on which he is seconded to the civil hospital.

Uniform and Equipment.

Medical officers will be required to provide themselves with the uniform of their rank and with the distinguishing badges of the Royal Air Force Medical Service. Officers accepting four-year short service commissions will be required to provide themselves with service dress and mess dress. For officers accepting two-year commissions mess dress will be optional. (The question of the grant of an outfit allowance to medical and other officers of the Royal Air Force is under consideration.)

Officers on entry are required to provide themselves with the regulation pocket case of instruments.

RATES OF PAY AND RETIRED PAY.

The rates of pay are as given in Table I. :—

TABLE I.

Years of service.	Rank.	Rate per diem.
On joining	Flying Officer.	s. 24
After 2 years	Flight Lieutenant.	26
" 4 years	"	28
" 6 years	"	30
On promotion	Squadron Leader.	34
After 2 years in the substantive rank	"	36
" 4 " " " " "	"	38

44	19	450	15	15
43	18	412	15	15
42	18	375	15	15
41	17	337	15	15
40	17	300	15	15

* Limited to five years.

Group Captains retire at 55; maximum retired pay £900.
Wing Commanders retire at 51; maximum retired pay £600.
Squadron Leaders retire at 48; maximum retired pay £500.

There will be a minimum qualifying period for retired pay of 20 years.

Gratuities.

Short-service officers will receive gratuities at the rate of £100 for each of the first two completed years of service, and at the rate of £150 for the third and fourth completed year. (If granted permanent commissions these gratuities will not be payable, but the period of service under the short-service commission will count for retired pay.)

Medical officers holding permanent commissions may, at the discretion of the Air Council, be allowed to withdraw from the Service after ten years' service with a gratuity of £1250 or after 16 years with a gratuity of £2000 in lieu of retired pay.

Allowances.

The usual allowances will be payable to medical officers under the same conditions as to officers of other branches of the Royal Air Force.

THE COLONIAL MEDICAL SERVICE.

IN the self-governing dominions, Canada, Australia, New Zealand, the Union of South Africa, and Newfoundland, medical appointments are made concerning which information can be obtained from the High Commissioners or Agents-General in London; appointments in Egypt and the Sudan are regulated from the Foreign Office; in Aden and adjacent territories the appointments are under the control of the Government of Bombay; in Rhodesia the appointments are made by the British South Africa Company, London Wall Buildings, E.C.; in North Borneo application should be made to the British North Borneo Company, 37, Threadneedle-street, E.C., for appointments; and those in Sarawak are in the hands of H.H. the Rajah.

But in addition to all these there are a large number of important posts under the patronage of the Secretary of State for the Colonies. These concern East Africa (the East Africa, Uganda, Nyasaland, Somaliland, and Zanzibar Protectorates); Eastern (Ceylon, the Straits Settlements, and Federated Malay States, Hong-Kong, Weihaiwei, Mauritius, and Seychelles); West India (British Guiana, Jamaica, Trinidad, the Windward Islands, the Leeward Islands, Barbados, British Honduras, and the Bahamas); Fiji and the Western Pacific, Cyprus, Malta, Gibraltar, St. Helena, Bermuda, and the Falkland Islands; and West Africa (Nigeria, the Gold Coast, Sierra Leone, and the Gambia). As a general rule, each Colony or Protectorate has its own public service distinct from that of every other, and it is usually only the higher officers who are transferred by the Secretary of State from one Colony to another; but there are two exceptions to this rule. The West African Medical Staff, which serves Nigeria, the Gold Coast, Sierra Leone, and the Gambia, form one service, and in practice the medical services of the Straits Settlements and the Federated Malay States may be regarded as one, as the officers may be and frequently are transferred from the Colony to the States, or *vice versa*. In Ceylon, Mauritius, Jamaica, Barbados, the Bahamas, and Bermuda vacancies are almost always filled locally by the appointment of qualified native candidates, or—in the case of some of the higher posts—by transfer from other Colonies. Appointments in Malta are all filled locally. Vacancies in the Hong-Kong Medical Department are generally filled by transfer from other Colonies. Medical appointments in the Bechuanaland Protectorate, Basutoland, and Swaziland are made only on the recommendation of the High Commissioner for South Africa, who usually appoints local candidates. In most cases the duties of a colonial medical officer are of a very general character, including medical, surgical, and often public health work. It is only occasionally that a specialist is required.

Applicants must be between the ages of 23 and 35 and doubly qualified, and the choice will usually fall on those who have held hospital appointments. Before being definitely appointed candidates will be medically examined by one of the consulting physicians of the Colonial Office: Sir J. Rose Bradford, K.C.M.G., 8, Manchester-square, London, W.; Sir J. Hawrey Benson, 57, Fitzwilliam-square, Dublin; Lieutenant Colonel J. Arnot, I.M.S., 8, Roehampton-place, Ealing; and W. T. Prout, Esq., C.M.G., 14, Rodney-street, Liverpool.

East Africa.—There are now vacancies for Medical Officers and Medical Officers of Health in East Africa. It is usual to select Medical Officers of Health from among officers already serving as Medical Officers, and in the wording of the regulations the term "Medical Officers" covers "Medical Officers of Health," save where the context indicates otherwise. Medical Officers selected for appointment to East Africa are allocated to one of the following administrations:—Kenya Colony and Protectorate, Nyasaland Protectorate, Somaliland Protectorate, Tanganyika Territory (late German East Africa), Uganda Protectorate, Zanzibar Protectorate. Whenever possible, a successful candidate is allocated to the Administration for which he expresses a preference. The conditions of service are here summarised: Appointments held by Medical Officers are on the permanent and pensionable establishment. Medical Officers serve for 3 years on probation, and leave is granted with full pay after every tour of service, the length of a tour being normally 30 months in East Africa. If an officer is not returning for further duty the leave for which he is eligible is the period of the voyage home and 2½ days in England for every month of service; if returning for further duty, the leave for which he is eligible is the period of the voyage home and back to East Africa and 5 days in England for every month of service in East Africa, but at certain stations service qualifies for leave at 3 and 6 days instead of 2½ and 5 days respectively. A free first-class passage is provided by the Government on first appointment and on leave. Quarters (with

furniture) are provided free of rent, or if quarters are not available, an allowance is given in lieu. Travelling allowance is paid to officers travelling on duty in East Africa in accordance with local regulations. Private practice is permitted subject to the proviso that it must not interfere with the officer's Government work, but this privilege is not granted to Medical Officers of Health. An Officer is eligible to retire on pension at the age of 50. Pension is calculated on the basis of 1/60th of pensionable emoluments at the date of retirement (i.e., salary and the value of free quarters) for each year of service, 2 years of service being reckoned for this purpose as three years. Medical Officers may, however, retire with gratuity, if they wish, instead of waiting to retire at the retiring age on pension. The gratuity is: After 9 years' service, of which not less than 6 years must be resident service in East Africa, £1000; after 12 years' service, of which not less than 8 years must be resident service in East Africa, £1250. Prior to appointment, candidates are required to attend a course of instruction in tropical medicine at the London or Liverpool School of Tropical Medicine; if this cannot be arranged, such a course must be taken during the first leave, before a Medical Officer can be confirmed in his appointment. Details of payments made by the Government in respect of these courses are supplied when a candidate has been provisionally selected. The Grades and Salary of the Medical Establishments are as follows:—East Africa, Protectorate and Tanganyika Territory and Uganda Protectorate: Principal Medical Officer, £1200; Deputy Principal Medical Officer, £1000; Principal Sanitation Officer, £1000; Senior Medical Officers, Sanitation Officers, £700–£25–£300; Medical Officers and Medical Officers of Health, £600–£25–£700. Nyasaland Protectorate: Principal Medical Officer, £1000; Senior Medical Officer, Sanitation Officer, £700–£25–£300; Medical Officers and Medical Officers of Health, £600–£25–£700. Somaliland Protectorate: Senior Medical Officer, £600–£25–£700. (£600 duty pay); Medical Officers and Medical Officers of Health, £500–£25–£700. Zanzibar Protectorate: Principal Medical Officer, £1000; Sanitation Officer, £700–£25–£300; Medical Officers and Medical Officers of Health, £600–£25–£700. All Medical Officers of Health receive a special non-pensionable allowance of £100 or £50 per annum according to their station in the Protectorates.

Straits Settlements and Federated Malay States.—The services of 33 medical officers are required here, the salary offered being \$440 a month for the first year, \$460 for the second, and \$480 for the third year. In all cases the appointments are on probation for the first three years; after which Medical Officers may be placed on the permanent and pensionable establishment. Subject to passing a strict efficiency test before rising above \$630 per month, salaries will thenceforward be at the rate of \$500 a month rising by annual increments of \$25 a month to \$870 a month. Promotion to posts above this maximum will be by selection. Officers having specialist qualifications of an approved type will enter the scale of salary at \$550, rising by \$25 a year to \$600 per month during the first three years; after which, if their appointments are made permanent and they pass the efficiency test, their salary will rise, as in other cases to \$800 a month. No duty allowance is paid. There is at present a strictly temporary increase to meet the increased cost of living: (a) 20 per cent on salaries under \$600; \$120 on salaries over \$600; (b) a married allowance for married officers of 20 per cent, with a maximum of \$160. The exchange value of the dollar is fixed by Government at 2s. 4d. This rate is liable to alteration but has remained constant for the past 14 years, and, so far as can be at present foreseen, no change is anticipated. Candidates must be graduates of one of the British Universities, or hold the qualifications of the College of Surgeons and Physicians of London, Edinburgh, or Ireland, and in some cases a diploma in Public Health. If they have not already done so, they will be required to attend a course of instruction at the London or Liverpool Schools of Tropical Medicine, either before embarkation or during their first leave of absence in Europe. Their whole time will be at the disposal of the Government, and no private practice is allowed. The duties will be generally to take charge of one of the hospitals in the Malay Peninsula, and any other duties on which in the public interest it may be desirable to employ them. Free passages (second class by mail or first class by other vessel) are given, with half salary from date of embarkation. Candidates of over 37 years of age will not be considered for appointment on the above terms. They may, however, be engaged on three years' agreement, renewable by consent of both parties, with salaries commencing at \$300 to \$700 a month (according to qualifications), and rising annually by \$25 a month. Such appointments will not be pensionable and no prospect can be held out of promotion to the highest posts in the Medical Service. A bonus of two months' salary, however, will be payable for each completed year's service on termination of agreement or extended agreement.

Seychelles.—There are four medical appointments. The Assistant Government Medical Officers receive Rs 5000. The holders of these appointments have free quarters. Private practice is allowed.

Weihaiwei.—There are two non-pensionable Medical Officers on salaries £400–£25–£500, with free quarters.

British Guiana.—The prospects of promotion in this Service are considerable. There are 3 posts at £400–£500, 17 posts at £500–£600, and 14 posts at £600–£700 per annum. There are several public hospitals and asylums; medical officers attached to these institutions receive plainly furnished bachelor quarters and an allowance in lieu of private practice. There are also many posts as resident surgeons in charge of districts. In these cases a travelling allowance is granted, and in some instances also a free house. There are four vacancies for Assistant Government Medical Officers at present, the appointments there being temporary for two years, at the end of which period the holders will be permanently appointed if their service has been satisfactory. The salary is £400, rising by annual increments of £25 to £500. A first-class passage to the colony is provided. Vacation leave of absence on full pay not exceeding three months may be granted by the Governor during and in respect of any two consecutive years' service. Subject to the necessities of the Service, leave of absence on half pay may be granted without any special grounds after six years' resident service from first appointment in the colony, and on special grounds at an earlier date.

Trinidad and Tobago.—In Trinidad and Tobago there are over 40 appointments. Officers are appointed in the first instance on two years' probation as supernumeraries and are eligible for appointment as Government Medical Officers at the end of this period. Applicants

must be unmarried and must remain unmarried whilst supernumerary Medical Officers. Supernumeraries receive a salary of £250 per annum with furnished quarters, and are usually attached to the Government hospital. Government Medical Officers receive salary at the rate of £250 per annum with quinquennial increments of £50 accruing from the date of first appointment as supernumerary Medical Officers. Most are employed as District Medical Officers, with private practice, a residence or a rent allowance of £50, a horse allowance, except in one district, and in some cases other allowances for institution work. All officers are required to contribute 4 per cent. of their salaries towards the pensions of the widows and orphans of public officers.

Windward Islands (Grenada, St. Lucia, St. Vincent).—The 25 appointments are, with few exceptions, district appointments with the right to private practice attached; the salaries paid by Government vary from £250 to £350, with allowances in certain cases. The Governor has the power to transfer a medical officer from one island to another at his discretion. The appointments are pensionable.

Leeward Islands (Antigua, St. Christopher and Nevis, Dominica, Montserrat, Virgin Islands).—The 24 appointments are of the same nature as in the Windward Islands, but are not pensionable. An officer when first sent out is not appointed to a particular island but to the service of the Leeward Islands, with a salary of £250 or £300 according to station, and the Governor decides as to the district which is to be allotted to him. He is liable to be transferred to any medical district in the Islands, and in certain districts he may be required to perform magisterial duties. The medical officers receive fees for successful vaccinations, post-mortem examinations, attendance and giving evidence at courts of justice, certificates of lunacy, and, in the larger islands, for burial certificates. They are also, as a rule, allowed private practice.

British Honduras.—There are seven medical appointments (besides the principal post of Colonial Surgeon) each carrying a salary of \$1701 per annum. Unless they already possess a Diploma of Public Health, medical officers are liable to be required before they join the colony to undergo a course of instruction at a laboratory of public health or analogous institution. The dollar = about 4s. 2d.

Fiji and the Western Pacific.—In Fiji the Government Medical Officers receive a salary of £400, rising by annual increments of £25 to £500, with partly furnished quarters, or a house allowance of £50. In some districts a medical officer is also a magistrate with a combined salary of £500, rising to £600, with free quarters. They are allowed private practice, so far as is consistent with the proper discharge of their duty to the Government, but in most districts the private practice is very small. In districts where there is no private practice, an allowance of £50 a year is granted. They are required either to take charge of hospitals or of districts, at the discretion of the authorities. The posts are pensionable. There are at present 18 Medical Officers, three of whom are also Magistrates, in addition to a Chief Medical Officer (£700 a year, rising to £800), a Medical Officer of Health (£500, rising to £600), and a Senior Medical Officer (£450-£500). The medical services of Fiji and the Western Pacific are interchangeable. While serving in the Western Pacific Protectorates their duties may be of a quasi-magisterial nature, and they draw an extra non-pensionable allowance of £50 per annum.

Cyprus.—There is a Chief Medical Officer paid at the rate of £550 per annum, and three District Medical Officers paid at the rate of £450 per annum, all enjoying private practice (except the Chief Medical Officer, who is allowed consulting practice only) and receiving 2s. per diem forage allowance; these are the only medical appointments in the island which are open to English candidates.

Gibraltar.—There is a surgeon of the Colonial Hospital receiving £400 with fuel and light allowances, and private practice. He also receives £50 for medical examination of school children. There are also two Assistant Surgeons with a salary of £350 per annum, who are allowed private consulting practice only. Free quarters, unfurnished, are provided for all three officers.

St. Helena.—The Colonial Surgeon at present receives £270 per annum, £20 fees as Health Officer, and £27 horse allowance. Private practice is allowed. The Assistant Colonial Surgeon receives £350 a year and a horse, with forage allowance; but no private practice is allowed without special permission.

Falkland Islands.—There are two appointments. The Colonial Surgeon is paid at the rate of £350 per annum, with £25 as Health Officer. The Assistant Colonial Surgeon is paid at the rate of £400 per annum without quarters. Part of the salary is provided from private sources. Private practice is allowed to the Colonial Surgeon, and to a lesser extent to the Assistant Colonial Surgeon.

Leave and Passages.—In the East African Protectorates leave of absence on full salary is granted in the normal case after a tour of residential service (of not less than 20 nor more than 30 months) to an amount of five days for each completed month of residence (or 2½ days when for any reason the officer is not returning to East Africa) exclusive of the periods of the voyages to and from. Officers serving in Uganda, Zanzibar, or in certain stations in the East Africa and Nyasaland Protectorates are allowed six or three days' leave respectively in respect of each month of service. In Somaliland special leave regulations exist which provide for an officer taking leave approximately every year. Free first-class passages are provided for the officer only. In the Malay Peninsula two months' leave of absence with full salary may be granted in respect of each year's service, and this leave may be accumulated up to a maximum of eight months. Additional leave on half pay may be granted on special grounds. If an officer on the occasion of his first leave is in receipt of a pensionable salary of less than £500 a year, he is granted a free return passage to the United Kingdom. In Hong-Kong leave of absence on half salary may be granted after 4½ years' service, and a portion of such leave may be commuted, if the Governor agrees, for half the amount on full pay. Leave of absence in excess of 10 months at a time will not be granted, but an extension may be allowed for ill-health or very urgent private affairs.

Subject to the necessities of the service, leave of absence on half salary may be granted to officers in other Colonies outside tropical Africa after a period of six years' residential service without any special grounds. Officers of the Fiji and Western Pacific service proposing to spend their leave in Europe may receive a grant in aid of passage expenses of £60. Leave may be given before the expiration of the due

period in case of serious indisposition, or of urgent private affairs. In the absence of special grounds, the leave must not exceed one-sixth of the officer's residential service; on special grounds it may exceed that period by six months. In addition to the above, vacation leave on full pay may be granted, if no inconvenience or expense is caused thereby, not exceeding three months in any two years. In the case of Fiji and the Western Pacific and the Falkland Islands, 4½ months' leave may be granted in any three years.

On first appointment an officer whose salary and fees together do not exceed £500 a year will, except in the case of a few Colonies possessing Representative Assemblies, be provided by the Crown Agents for the Colonies with free passages to the Colony for himself and his wife and children, if any, not exceeding four persons besides himself. The officer so appointed will be required to execute an agreement binding him to repay the cost of the passage or passages so obtained in the event of his leaving the Government service within three years. This rule applies also to officers appointed to the Malay Peninsula and Hong-Kong. An officer taking leave out of the Colony has to provide his own passages.

Pensions.—Officers on the pensionable establishment in the East African Protectorates are at liberty to retire on attaining the age of 50 years. Earlier retirement in the event of ill-health is also provided for. Pensions are computed on the scale of one-sixtieth of the average annual salary of the retiring officer's fixed appointments for three years prior to retirement, but for purposes of calculating pensions two years' service is reckoned as service for three years. In most of the other Colonies an officer holding a pensionable appointment may be allowed in the case of ill-health to retire on a pension after ten full years' residential service; otherwise he must have attained the age of 55. For ten full years' residential service fifteen-sixtieths of the average annual salary of the retiring officer's fixed appointments for three years prior to retirement may be awarded, to which one-sixtieth may be added for each additional year's service; but no addition will be made in respect of any service beyond 35 years. For pension purposes absence on vacation leave counts as full service, and leave on half pay as half service. In a few cases the retiring age is 60, and the pension after ten years' service is ten-sixtieths instead of fifteen.

Applications should be made in writing to the Private Secretary (Appointments), Colonial Office, Downing Street, London, S.W. 1.

West African Medical Staff.

The medical services of the West African Colonies and Protectorates—namely, the Gambia, Sierra Leone, the Gold Coast (including Ashanti and the Northern Territories), and Nigeria—form one service under the above name. All the medical officers for the service are selected by the Secretary of State for the Colonies, and are on one list for employment and promotion. As in other Colonies, applicants must be between 23 and 35 years of age and possess a double qualification, but preference is given to those over 25. The higher grades are usually filled by promotion from the lower. Camp outfit must be taken out by every medical officer, and an allowance of £30 is given towards its purchase on appointment.

The grades and emoluments of officers of the staff are as follows:—The Director of the Medical and Sanitary Service in Nigeria receives a salary of £1700 a year, with a duty allowance at the rate of £340 a year.

Principal Medical Officer: The Principal Medical Officers receive salaries as follows: In the Gold Coast and the Southern Provinces of Nigeria £1500 a year, with a duty allowance at the rate of £300 a year. In Nigeria (Northern Provinces), £1500 a year, with a duty allowance at the rate of £300 a year. In Sierra Leone, £1350 a year, with a duty allowance at the rate of £270 a year. There is no Principal Medical Officer in the Gambia.

Deputy Principal Medical Officer: There are four appointments of this grade, two in the Southern Provinces of Nigeria and one each in the Northern Provinces and in the Gold Coast respectively. Salary at the rate of £1300 a year is attached to these appointments, together with a duty allowance at the rate of £260 a year.

Senior Sanitary Officer: There are four appointments of this grade, two in Nigeria, one in the Gold Coast, and one in Sierra Leone. Salary at the rate of £1300 a year is attached to these appointments, together with a duty allowance at the rate of £260 a year.

Provincial Medical Officer: There are seven appointments bearing this title (four in Nigeria, two in the Gold Coast, and one in Sierra Leone), with salary at the rate of £1200 a year, and duty allowance at the rate of £240 a year.

Senior Medical Officer: There are 20 appointments of this grade, with salary at the rate of £1000 a year, rising by annual increments of £50 to £1150 a year, and proficiency pay of £100 a year. The Senior Medical Officer of the Gambia draws staff pay at the rate of £120 a year, in addition to duty pay, but is not allowed private practice.

Sanitary Officer: There are seven appointments of this grade, with salary at the rate of £1050 a year, rising by annual increments of £50 to £1200 a year, and a duty allowance at the rate of £210 a year.

Medical Officer: The salary is at the rate of £660 a year, rising by annual increments of £30 to £720; and then by £40 to £960, with proficiency pay of £72 a year. Before passing £800 Medical Officers are required to take a special course of study for three months; if satisfactory they then continue to draw increments up to £960. A Medical Officer who has served for three years on the maximum of this scale (£960) is eligible to be placed on the same scale of salary as a Senior Medical Officer.

Special appointments: The Director of the Medical Research Institute, Lagos, and the Pathologist, Accra, receive a salary of £1300 a year, with a duty allowance of £260 a year. Salary at the rate of £800, rising by annual increments of £40 to £960 a year, with a proficiency pay of £72 a year, is attached to about ten posts (those of Assistant at the Medical Research Institute, Lagos, and Medical Officers of Health at various places), irrespective of the seniority of the officer holding the appointment. Staff pay at the rate of £150 a year is also attached to these posts; and the holder of the appointment draws half of the staff pay during leave of absence, the remainder being drawn by his locum tenens.

Leave and Passages.—The ordinary tour of residential service is one year, followed by leave with full pay during the voyages to and from England, and for four or two months clear in England, according to the officer is returning for further service in West Africa or not. If an officer is detained beyond the year, additional leave is given with full pay for ten days in respect of each completed month beyond twelve, whether he is returning or not. If he is invalided before the end of the

year, the leave with full pay is for the voyages and for ten or five days in respect of each completed month, according as he is returning or not. Leave granted on the understanding that an officer will return is known as "return leave," and any pay drawn in respect of such leave is liable to be refunded if he does not return. Leave may be extended with half pay for a period not exceeding four months on the ground of ill-health, or without pay on that or other grounds. Free passages are given to all officers who are granted leave, and free passage is also given on first appointment, subject to the officer signing an agreement under which he is liable to refund its cost if he relinquishes his appointment for any other reason than physical or mental infirmity, or is removed for misconduct, within three years from the date of his arrival in West Africa. Half pay is given during the voyage out on first appointment.

Private Practice.—All officers of the Staff, except Principal Medical Officers, Deputy Principal Medical Officers, Provincial Medical Officers, Sanitary Officers, and a few other officers holding special appointments, are at present allowed to take private practice, provided that it does not interfere with the efficient performance of their official duties, but it is within the power of the Governor to withdraw or suspend the privilege in such places and for such periods as he may consider desirable. Private practice does not exist at the majority of stations, and as a general rule, subject to the exigencies of the service, stations where there is private practice are allocated to senior members of the staff.

Pensions and Gratuities.—These vary in accordance with the regulations of each Colony, but generally speaking an officer on attaining the age of 50 years, or after 18 years' service (of which at least 12 must have been residential) is qualified for a pension calculated at one-fortieth of the last annual salary for each year of service. If invalidated after a minimum of seven years' service, he is qualified for a pension calculated at the same rate. If invalidated before completing seven years' service, he is qualified for a gratuity not exceeding three-quarters of a month's salary for each six months of service; provided that he has been confirmed in his appointment. For the purpose of calculating the amount of these pensions and gratuities, leave of absence without salary is not counted, while leave with half salary is counted at the rate of one month for every two months of such leave. An addition, representing the value of free quarters, is made to the officer's salary. This addition is as follows: To salaries of £400 a year, an addition of £40; to salaries above £400, but not exceeding £500, an addition of £50; to salaries above £500, but not exceeding £700, an addition of £60; to salaries above £700, but not exceeding £900, an addition of £70; to salaries exceeding £900, an addition of £80. In addition to the ordinary regulations, an officer of the West African Medical Staff enjoys the following special privilege. At the end of nine years (of which not less than six must have been residential) he will be permitted to retire with a gratuity of £1000, or at the end of 12 years (of which not less than eight must have been residential) with a gratuity of £1250. All claims to pensions are, however, forfeited on the receipt of such a gratuity. In the event of an officer dying in the service after completing the period of residence qualifying him for the smaller or the larger of these gratuities, a sum equal to the gratuity in question will be paid to the credit of his estate. Officers are not allowed to take their wives out with them until they have acquired experience of the local conditions, and have obtained the sanction of the Governor. Passages for wives and children are not provided.

Candidates for medical appointments in West Africa are allowed to express a preference for any particular Colony or Protectorate, and their wishes in this respect will be borne in mind and met as far as possible, but they are liable to be posted in the first instance, or transferred afterwards if necessary, to any other West African Colony or Protectorate at the discretion of the Secretary of State. Candidates who wish to be posted to the Northern Provinces of Nigeria should be able to ride. Candidates should on no account apply for, or accept, a West African appointment in the expectation of ultimately being transferred elsewhere, as the number of such transfers is exceedingly small. No applications for transfer can be entertained until an officer has served for five years in the West African Medical Staff, and officers desiring to be transferred must be prepared to find that medical salaries in other Colonies are lower than in West Africa. Only a small proportion of applicants succeed in obtaining a transfer. Officers who may be transferred to pensionable appointments under the Crown elsewhere than in West Africa do not forfeit their claim to pension in respect of their West African service on final retirement, provided they have been members of the Staff for at least 12 months.

Instruction in Tropical Medicine.—Every candidate selected for appointment will, unless the Secretary of State decides otherwise, be required to undergo a course of instruction for two or three months either at the London School of Tropical Medicine, Endsleigh-gardens, Euston-square, N.W. 1, or at the Liverpool School of Tropical Medicine at the University of Liverpool. The cost of tuition will be borne by the Government, but candidates must make their own arrangements for board and lodging; an allowance of £3 a week will be paid to them monthly in arrear for this purpose. A daily allowance of 5s. (but no salary) will be paid to each candidate, monthly in arrear, during the course, and may be continued subsequently up to the date of embarkation. These payments must be refunded by the candidate if he declines to accept an appointment in any of the Colonies or Protectorates for which he may be selected, if he fails to obtain a certificate showing that he has satisfied the school authorities, or if he relinquishes the West African service for any other reason than mental or physical infirmity, or is removed for misconduct, within three years of the date of his arrival in West Africa. If at the end of the session there exist no vacancy in the staff to which a candidate can be appointed, he will be placed in a Reserve and granted an allowance at the rate of £200 a year until the occurrence of a vacancy.

Course of study for higher scale of salary.—The approved course of study is the three months' course of the West London Post-Graduate College or the London School of Clinical Medicine, Greenwich, in clinical medicine, clinical surgery, and pathology. Officers are allowed

to substitute for this course either the course of study and examination for a recognised diploma or degree in public health, sanitary science, or State medicine; the course of study and examination for a further medical or surgical diploma or degree; or if the Governor, on the recommendation of the Principal Medical Officer, approves—a course of study in some special branch of medical or surgical practice (e.g., ophthalmology, dermatology, genito-urinary diseases), or an advanced course at the London or Liverpool School of Tropical Medicine. Whichever of these courses of study is selected, the necessary tuition and examination fees will be paid by the Colonial Government except in the event of an officer's deciding to enter for a further medical or surgical diploma or degree.

In conclusion it should be added that owing to the wastage of war and the lapse of periods of service there are at the present time many vacancies in the Colonial service, and that the age limits laid down for Colonial appointments are not always insisted upon, while in a number of cases a temporary war bonus augments the salary. It should be noted, too, that there is some possibility that in the near future opportunities may be given to Colonial officers for research work, thus bringing this branch of public medical service more in line with the opportunities offered to the military and naval services.

DIPLOMAS IN STATE AND TROPICAL MEDICINE.

As usual we include in the Students' Number of THE LANCET an epitome of the instruction given at various universities and centres of medical education to medical men desiring to obtain diplomas in sanitary science, public health, State medicine, and tropical medicine.

Resolutions, designed with a view of ensuring "the possession of a distinctively high proficiency, scientific and practical, in all the branches of study which concern the public health," have been adopted at various times by the General Medical Council from 1902 to 1911. Certain universities and corporations grant qualifications in Tropical Medicine which have not as yet been made registrable by statute.

University of Oxford.—An examination, conducted partly in writing, partly *visà voce*, and in each subject partly practical, is held in Michaelmas and Trinity Term in the following subjects:—General Hygiene, General Pathology (with special relation to Infectious Diseases), the Laws relating to Public Health, Sanitary Engineering, Vital Statistics. The examination is in two parts, which may be taken together or separately; but Part I. must be passed either before or at the same examination as Part II. The fee for admission to the examination is £5 for each part. Successful candidates are entitled to receive the Diploma in Public Health.

The First Part of the examination will comprise (a) a written paper of three hours in Chemistry and Physics; (b) a three hours' practical and *visà voce* examination in Chemistry and Physics.

The Second Part of the examination will consist of the following parts:—(a) Two written papers, each of three hours, dealing with General Hygiene (including Sanitary Engineering, Vital Statistics, and the Laws relating to Public Health); (b) a practical and *visà voce* examination in General Hygiene; (c) a written paper of three hours in Pathology and Bacteriology; and (d) a three hours' practical and *visà voce* examination in Pathology and Bacteriology.

Candidates in Part I. of the examination will be required to produce a certificate (1) of Laboratory Work in Chemistry as applied to Hygiene.

Candidates in Part II. will produce the following further certificates: (2) of a Practical Knowledge of the Duties, Routine and Special, of Public Health Administration; (3) of having had Practical Instruction in Bacteriology, and the Pathology of the Diseases of Animals transmissible to Man; and (4) of having attended the practice of a Hospital for Infectious Diseases at which opportunities are afforded for the study of the Methods of Administration. All the above degrees are now open to Women Students, and particulars of Scholarships, &c., may be obtained from the Principals of the various Ladies' Colleges. The names of candidates must be sent to the Assistant Registrar of the University, Clarendon Building, Oxford, to whom applications for any further information should be addressed.

¹ Except that the pension of an officer who has been promoted within three years of his retirement is calculated on the average of his salary for the last three years.

University of Cambridge.—Two examinations in so much of State medicine as comprised in the functions of medical officers of health are held during the year. The examination is divided into two parts and demands proficiency in all the branches of study which bear upon the duties of medical officers of health. The examinations in both parts will be oral and practical, as well as in writing. Candidates may present themselves for either part separately or for both together at their option; but the result of the examination in the case of any candidate will not be published until he has satisfied the examiners in both parts. Marks of distinction will be placed against the names of candidates who have specially distinguished themselves in either (1) general principles of hygiene; (2) bacteriology; (3) chemistry in Part I. of the examination; or (4) the second part of the examination, which has reference to State Medicine and to the applications of Pathology and Sanitary Science. Every candidate will be required to pay a fee of £6 6s. before admission or readmission to either part of the examination, but candidates who have presented themselves before the year 1896 will be readmitted to either part on payment of a fee of £5 5s. Candidates must before admission to either part of the examination produce evidence of having satisfied provisions (1), (2), and (3), and before admission to Part II. having satisfied provision (4), above mentioned.

For Part I. of the examination courses of lectures and laboratory instruction are given in the University by Mr. J. E. Purvis on Hygiene, Chemistry, &c., and by Dr. Graham-Smith on Bacteriology. Professor G. H. F. Nuttall gives a course of lectures on Protozoal Diseases, and Dr. A. E. Shipley on Animal Parasites. For Part II. Dr. A. J. Laird, the Medical Officer of Health for Cambridge, gives courses on Practical Sanitary Administration and in the Administrative Methods of the Infectious Diseases Hospital, and Dr. F. Robinson, the Medical Officer of Health to the Cambridgeshire County Council, on Sanitary Laws, School Hygiene, Epidemiology, Vital Statistics, &c. These courses are open to non-members of the University.

All applications for further information respecting examinations and the courses of study should be addressed to Mr. Purvis, Chemical Laboratory, Pembroke-street, Cambridge.

Two Examinations in Tropical Medicine and Hygiene are conducted yearly by the State Medicine Syndicate of the University of Cambridge. The examinations are held in Cambridge early in January and in the middle of August. Each examination will extend over four days.

Any person whose name is on the Medical Register is admissible as a candidate to the examination provided (I.) that a period of not less than 12 months have elapsed between his attainment of a registrable qualification and his admission to the examination; (II.) that he produce evidence, satisfactory to the Syndicate, that he has diligently studied Pathology (including parasitology and bacteriology) in relation to Tropical Diseases, Clinical Medicine, and Surgery at a Hospital for Tropical Diseases, and Hygiene and Methods of Sanitation applicable to Tropical Climates. As evidence of study and attainments a candidate may present to the Syndicate (1) any dissertation, memoir, or other record of work carried out by himself on a subject connected with Tropical Medicine or Hygiene; (2) any Certificate or Diploma in Public Health or Sanitary Science he may have obtained from a recognised Examining Body. Such evidence will be considered by the Syndicate in determining whether he is qualified for admission to the examination and by the examiners in determining whether, if admitted, he shall be included in the list of successful candidates.

The examination will be partly in writing, partly oral, and partly practical and clinical (the clinical part will be conducted at a hospital for tropical diseases, at which cases will be submitted for diagnosis and comment), and will have reference to the nature, incidence, prevention, and treatment of the epidemic and other diseases prevalent in tropical countries. Every candidate who passes the examination to the satisfaction of the examiners will receive from the University a diploma testifying to his knowledge and skill in tropical medicine and hygiene.

The fee for the examination is £9 9s., and applications should be addressed to Dr. Graham-Smith, Medical Schools, Cambridge.

University of London.—Candidates for the M.D. degree may offer State medicine as a subject in which to graduate. They must send to the Academic Registrar with their forms of entry certificates (i.) of having, subsequently to having obtained a registrable qualification to practise Medicine, attended a course of practical instruction in a laboratory or laboratories, British or foreign, approved by the University, in which chemistry, bacteriology, and the pathology of the diseases of animals transmissible to man are taught; such course to extend over a period of not less than six months and to consist of at least 240 hours, of which not more than one-half shall be devoted to practical chemistry. (ii.) Either of having, subsequently to having obtained a registrable qualification to practise Medicine, during six months (of which at least three months shall be distinct and separate from the above-mentioned period of laboratory instruction) been diligently engaged on not less than 60 working days in acquiring a practical knowledge of the duties, routine and special, of Public Health Administration under the supervision of a person recognised by the University as entitled to grant certificates. Or of having held for a period of not less than three years an appointment as Medical Officer of Health of a Sanitary District within the British Dominions, and having a population of not less than 15,000. (iii.) Of having, subsequently to having obtained a registrable qualification to practise Medicine, attended at least twice weekly during a period of not less than three months a practice of a hospital for infectious diseases at which opportunities are afforded for the study of methods of administration. In connexion with this degree the various metropolitan medical schools hold regular classes under teachers of Public Health and Sanitary Science, such instruction being also used to obtain the various diplomas of other Universities and of those Royal Corporations which grant them.

University of Durham.—Candidates for the degree of Bachelor of Hygiene (B.Hy.) must be at least 22 years of age, registered, and a graduate in Medicine of a recognised university. They must spend six months at Newcastle-upon-Tyne studying Comparative Pathology, Practical Bacteriology, Sanitary Chemistry, and Physics, and have to pass an examination in Sanitary Chemistry, Physics, Comparative Pathology, Sanitary Legislation, Vital Statistics, Nosology, Climatology, Meteorology, Distribution of Health and Disease, Sanitary Medicine and Practical Hygiene. The fee for the examination for the degree of B.Hy. is £10 10s. and for the degree £6 6s. Candidates for the degree of Doctor of Hygiene (D.Hy.) must have acquired the degree of Bachelor of Hygiene, must for two years subsequently have been engaged in Public Health administration, or in research work relating to Public Health. The fee for the examination for the degree of D.Hy. is £5 and for the degree £10. The regulations for examination for the Diploma in Public Health (D.P.H.) are the same as those for the degree of Bachelor of Hygiene, except that the candidate is not required to be a graduate in Medicine of a recognised University and the course of study need not be passed at Newcastle-upon-Tyne. The fee for the examination is £10 10s. and for the diploma £3.

Victoria University of Manchester.—An examination in Public Health is held twice yearly. The examination is in two parts and is written, oral, and practical. Candidates may present themselves for Parts I. and II. separately or at the same time provided that no candidate be admitted to Part II. unless he has already passed in Part I. No candidate's name will be published until he has satisfied the examiners in both parts of the examination. The fee for each part is £5 5s., and must be paid on or before July 1st in each year. For any subsequent examination in the same part the fee will be £3 3s. Every candidate who has passed both parts of the examination to the satisfaction of the examiners, and who is legally registered, will receive a Diploma in Public Health. The examinations will begin about the end of March and the middle of July in each year. Holders of the Diploma in Public Health are eligible for examination for the Certificates in School Hygiene and Factory Hygiene after attending the prescribed periods of study and hospital practice.

University of Birmingham.—The University grants a degree of B.Sc. in Public Health and also a Diploma in the

same subject on the following conditions: Graduates in Medicine of this University may become candidates for the degree of Bachelor of Science in Public Health by conforming to all the requirements laid down for candidates for the Diploma in Public Health, except that after graduating in Medicine all courses of study must be taken out in the University, and they must, in addition, have attended a three months' course of Geology in the University. The examinations will be held in the months of March and June and will consist of two parts, each part being written, oral, and practical. No candidate will be allowed to pass Part II. until he has passed Part I. Candidates may enter for Parts I. and II. separately or at the same time. The fee for each part of the examination is £5. Medical Officers of the Royal Navy who have attended courses in Hygienic Chemistry, Bacteriology, and Public Health at the Naval Medical School, Greenwich, will be admitted to the examinations for the Diploma in Public Health, whether they have previously been students at the Birmingham School or not; and the same applies to officers of the Royal Army Medical Corps who have studied Chemistry and Bacteriology at the Staff College and pursued the further course of study approved by the General Medical Council.

University of Liverpool.—The University grants a Degree in Hygiene (M.H.) and a Diploma (D.P.H.), and every facility is afforded for training in Sanitary Science and State Medicine. The curriculum for the Degree extends over a period of two years, the first of which is devoted to laboratory instruction and practical classes (including those for the Diploma); the second being devoted to advanced study and research. The D.P.H. curriculum fees are: Chemistry, £5 5s.; Bacteriology, £5 5s.; Practical Sanitation, £15; Infectious Diseases, £3 3s. The courses may be taken out at any time, and students are allowed to work daily in the laboratories.

The University grants a Diploma in Tropical Medicine. Three courses of instruction are given every year. Two of these last for three full months—the Lent Course from Jan. 6th to April 5th and the Autumn Course from Sept. 15th to Dec. 13th. The Third Course, an Advanced Course, lasts one month, from June 1st to the 30th. At the end of each full course an examination is held by the University for its Diploma of Tropical Medicine (D.T.M.), which is open only to those who have been through the course of instruction of the school. The examination lasts three days and consists (1) of papers on Tropical Medicine, Tropical Pathology, and Tropical Sanitation and Entomology respectively; (2) of a clinical examination; and (3) of an oral examination. The advanced course consists entirely of Practical and Clinical Laboratory Work, given at the laboratory at the University. The fee for the full course of instruction is 13 guineas, with an extra charge of 10s. 6d. for the use of a microscope if required. The fee for the examination is 5 guineas. Applications must be made to the Dean of the Medical Faculty, University of Liverpool. Two University Fellowships of £100 a year each are open to students of the school, amongst others. Accommodation for research work is to be had at the University Laboratory. The Mary Kingsley Medal is awarded by the school for distinguished work in connexion with Tropical Medicine.

University of Leeds.—The University grants a Diploma in Public Health, and every facility is afforded for training in Sanitary Science and State Medicine. The examination, which is held twice in each year—namely, in June and December—is in two parts, and is written, oral, and practical. Candidates may present themselves for Part I. (a), Part I. (b), and II. separately or at the same time, provided that no candidate be allowed to pass in Part II. unless he has already passed in Part I. Fees.—The fee for each part is £5 5s., and for any subsequent examination in the same part £3 3s. Instruction in Sanitary Chemistry and Bacteriology is given in the second and third terms. Practical work under arrangement with the Leeds City Council. Prospectus can be obtained from the Dean of the Medical School.

University of Bristol.—Diploma in Public Health. Candidates must be at least 23 years of age, shall be fully registered medical practitioners of not less than 12 months' standing as such, and shall have passed the examination prescribed by regulation. The examination is divided into two parts. The subjects of the First Part are Chemistry as

applied to Public Health and Pathology and Bacteriology. Candidates for the First Part shall, during six months after having obtained a registrable qualification, have received practical laboratory instruction in Hygienic Chemistry, in Bacteriology, and in the Pathology of the Diseases of Animals Transmissible to Man. The subjects of the Second Part are: Public Health and Epidemiology, Sanitary Law, Vital Statistics, and Sanitary Reporting.

For information as to Post graduate instruction apply to the Director of Post-graduate Studies, Professor Walker Hall.

University of Edinburgh.—Two degrees in Science in the Department of Public Health are conferred by the University of Edinburgh—viz., Bachelor of Science in Public Health and Doctor of Science in Public Health. A Diploma in Tropical Medicine and Hygiene is also granted. Candidates for the degree of B.Sc. in Public Health must be graduates in Medicine of a recognised University, and must pass two examinations, for the first of which they must, after graduation in Medicine, have worked for at least 20 hours per week during a period of not less than eight months, of which at least five consecutive months must be in the Public Health Laboratory of the University of Edinburgh and the remainder either there or in a laboratory recognised by that University; they must also have attended courses of instruction in Physics and Geology in some Scottish University. Candidates are not admitted to the Second Examination sooner than six months after having passed the First Examination, nor sooner than 18 months after having taken their degree in Medicine, and they must have attended two separate courses in Public Health in some University of the United Kingdom or in such medical school or Indian, Colonial, or Foreign University as may be approved for the purpose by Edinburgh University, each course consisting of 40 lectures at least; one of which courses shall deal with medicine and the other with engineering, each in its relation to public health. The subjects of examination include Laboratory work, Physics, Geology, Medicine in its application to Public Health, Sanitation, Sanitary Law, and Vital Statistics. Graduates who have held the degree of B.Sc. in Public Health from the University of Edinburgh for a term of five years may offer themselves for the degree of D.Sc. in Public Health in that University. They must then present a Thesis and pass an examination in Public Health. The fees are £3 3s. for the First and £3 3s. for the Second B.Sc. Examinations, and £10 10s. for the degree of D.Sc.

University of Aberdeen.—The Diploma in Public Health (D.P.H.) is conferred only on graduates in Medicine of a University in the United Kingdom not less than 12 months after medical graduation. Every candidate must produce evidence of having complied with the following requirements: (1) A course or courses of instruction consisting of not fewer than 50 meetings dealing with public health in relation to the administrative and other duties of a medical officer of health, such course or courses to be given by a teacher or teachers in the department of public health of a recognised medical school. (2) Practical instruction within a laboratory or laboratories approved by the University, in (a) Bacteriology, (b) Physics and Chemistry, (c) Parasitology, such instruction to extend over not less than six months or two academic terms. (3) Practical Instruction, Clinical and Administrative, within (a) a hospital for general infectious diseases—not less than thrice weekly; (b) a hospital or sanatorium or treatment centre for tuberculosis—not less than once weekly; (c) a hospital or treatment centre for venereal diseases—not less than once weekly; such instruction in each group to extend over three months. (4) Practical instruction and experience during not less than three months in the duties, routine and special, of public health administration, under the personal supervision of a medical officer of health or other medical officer, or, alternatively, that the candidate has held, within the British Dominions, for a period of not less than three years, an appointment as medical officer of health of a sanitary district with a population of not less than 15,000. (5) Practical instruction in: (a) Mother and Child Welfare at a Centre or Centres in a Welfare Scheme conducted or approved by a Local or Sanitary Authority—not fewer than ten meetings; (b) School Hygiene and Medical Inspection of School Children—not fewer than six meetings; (c) Drawing and Interpretation of Plans—not fewer than six meetings. The fee for the examination is £4 4s. for each part, or £8 8s. for the whole examination.

University of Dublin (Trinity College).—The Diploma in Public Health is conferred, after examination, on the following conditions. The candidate must be a registered medical practitioner and have obtained a registrable qualification at least nine months before the second part of the examination. The candidate must have completed, subsequently to obtaining a registrable qualification, four months' practical instruction in a chemical and bacteriological laboratory, or laboratories, approved by the University, must have studied practically outdoor sanitary work for six months under an approved officer of health, and must have attended for three months at a fever hospital where opportunities are afforded for the study of methods of administration. A special prospectus and a list of recognised laboratories may be obtained by application to the Registrar of the School of Physic, Trinity College, Dublin.

National University of Ireland.—At this University there is a Diploma in Public Health and a B.Sc. in Public Health. The Diploma may be granted to matriculated or non-matriculated students of the University who shall have completed approved courses of study and shall have passed the prescribed examinations, provided that it shall not be granted except to a registered medical practitioner. Candidates may present themselves for the examination after an interval of not less than 12 months from the time of obtaining a registrable qualification. The curriculum extends over a period of not less than nine calendar months. Every candidate must produce a certificate that he has attended practical instruction in a laboratory, approved by the University, in Chemistry, Bacteriology, and the Pathology of the diseases of animals transmissible to man. The examination consists of two parts, which may be passed separately or together. Part I. comprises the following subjects: Chemistry, Meteorology and Climatology, and Sanitary Engineering and Architecture. Part II. comprises the following subjects: Bacteriology, Hygiene, Sanitary Law, and Vital Statistics. The examination in each part will be oral and practical as well as written.

For the B.Sc. in Public Health a candidate shall not be admitted unless he (a) shall have received the degrees of M.B., B.Ch., and B.A.O. at least one year previously; (b) shall have pursued an approved course of study in the Faculty of Medicine; and (c) shall have passed the prescribed examination. In addition to D.P.H. course the candidate will be required to take up (1) a Special Course of Pathology; (2) Bacteriology; and (3) Advanced Course in Hygiene. Each of these courses lasts three months.

University of Belfast.—A Diploma in Public Health is given by examination. Every candidate must produce evidence that, after obtaining a registrable qualification, he has during six months received practical instruction in an approved laboratory in which Chemistry, Bacteriology, and the Pathology of the diseases of animals transmissible to man are taught. After obtaining a registrable qualification every candidate must produce evidence that he has attended during three months the practice of a hospital for infectious diseases at which opportunities are afforded for the study of methods of administration. The examination must have extended over not less than four days, one of which shall have been devoted to practical work in a laboratory, and one to practical examination in, and reporting on, subjects which fall within the special outdoor duties of a medical officer of health. The examination will be held once yearly, Part I. in March and Part II. in June. The first part of the examination will have reference to the general principles of sanitary science, and the second part to State Medicine and to the applications of Pathology and Sanitary Science. The fee for each part is 1 guinea.

Royal College of Physicians of London and the Royal College of Surgeons of England.—The following are the regulations for obtaining the Diploma in Public Health: The examination consists of two parts. The first part of the examination takes place in January and July, and the second part in January and July. The fee for each part is £10 10s., except for those who are diplomates of the Royal Colleges, who pay £6 6s. for each part. A candidate intending to present himself must give 14 days' written notice to the Secretary, at the Examination Hall, Queen-square, London, W.C.1. He will be admissible to examination in Part I. on producing evidence (1) of having been in possession of a registrable qualification for at

least 12 months; and (2) of having attended thereafter practical instruction in a laboratory recognised by the Examining Board in England for at least 240 hours during a period of six months. A candidate will be admitted to Part II. of the examination on producing evidence (1) of having been diligently engaged in acquiring a practical knowledge of Public Health administration during six months under certain specified conditions; and (2) of having attended during three months the clinical practice of a hospital for infectious diseases.

Royal College of Physicians of Edinburgh, Royal College of Surgeons of Edinburgh, Royal Faculty of Physicians and Surgeons of Glasgow.—All candidates for the Diploma in Public Health must have a qualification which has been registered under the Medical Acts. Candidates must have attended not less than four calendar months' practical instruction in Chemistry and Bacteriology in a recognised laboratory or laboratories, must have studied outdoor sanitary work for six months under a medical officer of health or other sanitary officer; and must give evidence of attendance for three months at the practice of a Hospital for Infectious Diseases, at which he has received instruction in the methods of administration. The examination consists of two parts, and candidates may enter for both at one period or for either separately. The First Part includes (a) Laboratory Work (Chemistry and Bacteriology), (b) Physics and Meteorology; and the Second Examination embraces (a) Report on Premises visited, (b) Examination at Fever Hospital, (c) Examination at Public Abattoir, (d) Written and Oral Examinations on Epidemiology and Endemiology, (e) Vital Statistics and Sanitary Law, and (f) Practical Sanitation. The fee is 12 guineas for both examinations, or 6 guineas for either of them. A fee of 3 guineas is payable by rejected candidates for either examination. The examination is held twice yearly, in May and October. The published regulations provide detailed synopses of the subjects of examination. The Registrar for Edinburgh is Mr. D. L. Eadie, 49, Lauriston-place, and for Glasgow Mr. Walter Hurst, 242, St. Vincent-street.

Royal College of Physicians of Ireland and Royal College of Surgeons in Ireland.—Every candidate for the Diploma in Public Health must be a registered medical practitioner. He must subsequently to qualification (1) receive four months' laboratory instruction in Chemistry, Bacteriology, and the Diseases of Animals transmissible to man; and (2) during six months practically study outdoor sanitary work under a medical officer of health, and shall as an additional requirement attend a hospital for infectious diseases. Candidates are examined on four days, commencing on the first Monday of February, May, and November. The examination comprises the following subjects:—Hygiene, Chemistry, Meteorology and Climatology, Engineering, Vital Statistics, Sanitary Law, and Bacteriology. The fee for the examination is £10 10s. For further particulars apply to Alfred Miller, O.B.E., Secretary, Committee of Management; Office, Royal College of Surgeons, Dublin.

DIPLOMAS IN PSYCHOLOGICAL MEDICINE.

THE needs for Schools of Psychiatry were well stated two years ago in the annual report of the Board of Control, when attention was called to deficiencies in the arrangements as at present organised for the treatment of persons suffering from mental disorder, especially in its early stages. During the two years that have elapsed both the loss to the country and the hardship to individuals resulting from insufficient attention to incipient mental cases have been recognised by the medical profession and all sections of the thinking public, so that any educational development improving the scientific position of psychological medicine will meet with warm approval.

Diplomas in Psychological Medicine, though of comparatively recent date, have been instituted at various centres for some ten years, while affiliation of mental clinics to the teaching in general hospitals has been much recommended. When this takes place there will be no dearth of suitable applicants for posts at asylums, for many young men can then be trained to take up the work in sympathetic

and scientific spirit. But before the lunacy service can become attractive, the views of the Board of Control, which have been stated to the Visiting Committees of Asylums, must receive practical expression by a general improvement in salaries, in accommodation for married officers, and by the provision in asylums for the more effective treatment upon modern lines of recoverable cases. The following bodies have now arranged to grant diplomas in psychological medicine or psychiatry—namely, the Universities of Manchester, Leeds, Edinburgh, Cambridge, Durham, and London, and the Royal College of Physicians of London. The regulations for obtaining these diplomas point to much similarity in the scope of the examinations, though there are differences in the duration of the courses and the syllabus, details of which can be obtained from the various examining bodies.

The necessity for raising the standard of the training for Assistant Medical Officers in asylums, and of affording facilities for such training, is very real. If the authorities give proper preference to the candidates for vacancies who possess diplomas or degrees in mental disease the status of this branch of the medical profession will be automatically raised, and pay and conditions of service will have to be made commensurate. It is necessary that the Authorities should make arrangements to grant study-leave on full pay to their Assistant Medical Officers, especially if it is the object of these officers to obtain a diploma which they were previously without; and augmented salary might well be paid to successful examinees. In the face of the facts acquired in recent years as to mental health, it is necessary that psychological medicine should now form an integral part of medical education, so that no university should willingly be without such an organic unit as a School of Psychiatry.

DENTAL SURGERY.

ANYONE who is on the Medical Register is entitled to practise as a dentist, although he cannot register as such without a licence in dentistry; but it is of eminent advantage to take the L.D.S., otherwise few dental appointments at general or special hospitals or dispensaries are available. The subjects beyond those included in the general qualification are—Dental Anatomy and Physiology (Human and Comparative), one course; a separate course of Dental Histology, including the preparation of microscopical sections; Dental Surgery, one course; a separate course of Practical Dental Surgery; a course of not less than five lectures on the Surgery of the Mouth; Dental Mechanics, one course; a course of Practical Dental Mechanics, including the manufacture and adjustment of six dentures and six crowns; Dental Metallurgy, one course; a course of Practical Dental Metallurgy; Practice of Dental Surgery at a recognised school, two years, and a certificate of having been engaged during a period of not less than two years in acquiring a knowledge of Dental Mechanics (this may be obtained by apprenticeship to a duly qualified dental practitioner or in the mechanical department of a recognised dental hospital). The Dental Schools in London are the Royal Dental Hospital of London, the National Dental Hospital, Guy's Hospital Dental School, and the London Hospital Dental School. Most of the large provincial towns, where there are medical schools, have now dental hospitals.

The Registration of Dental Students is carried on at the Medical Council Office in London in the same manner as the existing registration of medical students, and subject to the same regulations as regards Preliminary Examinations. Candidates for a diploma in Dental Surgery must produce certificates of having been engaged during four years in professional studies, including two years' instruction in mechanical dentistry. The two years of instruction in mechanical dentistry, or any part of them, may be taken by the dental student either before or after his registration as a student. When a student can show evidence of regular pupilage in mechanical dentistry to a registered practitioner prior to the passing of a preliminary examination he may be allowed to antedate for a period not exceeding one year prior to the passing of a preliminary examination. The recommendations as to the

course of study and examinations adopted by the General Medical Council in November, 1909, are under revision by the Council, but consideration of them is postponed until the Departmental Committee on the Dentists Act has reported.

It is necessary for anyone practising Dental Surgery in this country to be on the Register, and no foreign qualifications are recognised, except the Dental Diploma granted in Belgium after examination by the Provincial Medical Commission, provided the holder has obtained the grade of "Candidate in Medicine" at one of the four Belgian Universities. Persons with Colonial and Foreign qualifications which have been obtained after a four years' curriculum can apply for special registration. Certain dental qualifications granted in Australia and New Zealand are also registrable. The Royal Colleges of the United Kingdom and ten of the Universities grant degrees or licences in Dental Surgery.

THE REGISTERING BODIES IN DENTISTRY.

The Royal College of Surgeons of England grants a diploma in Dental Surgery under the following regulations, which apply to all candidates who have registered as dental students after Jan. 1st, 1897. Candidates are required to pass three examinations: the Preliminary Science Examination, the First Professional Examination, and the Second Professional Examination. I. Preliminary Science Examination.—This is identical with Part I. of the First Examination of the Examining Board in England. Candidates who commenced professional study on or after Oct. 1st, 1913, must pass the Preliminary Science Examination before commencing the courses required for the Second Professional Examination. II. The First Professional Examination.—The candidate must produce evidence of instruction in Dental Metallurgy and Practical Dental Mechanics. The Examination consists of Part I. (Mechanical Dentistry) and Part II. (Dental Metallurgy), the examination in Dental Metallurgy being by written paper. The parts may be taken together or separately. III. The Second Professional Examination.—This is divided into two parts: (a) the General, (b) the Dental. The General part must be passed before the Dental portion. The instruction is obtained partly at a General Hospital and partly at a Dental Hospital.—The Second Professional Examination consists of: Part I., General Anatomy and Physiology, General Surgery and Pathology; Part II., Dental Anatomy and Physiology, Dental Pathology and Surgery, and Practical Dental Surgery. There is a written and *viva voce* examination in each part and a practical examination as well in Part II. Exemption from the Preliminary Science Examination is granted to candidates who have passed an Examination in Chemistry and Physics for a degree in Medicine at a University in the United Kingdom, in India, or in a British colony. Exemption from Examination in Anatomy and Physiology is granted to candidates who have passed the Second Examination of the Examining Board in England or the corresponding Examination for any degree or qualification in Medicine or Surgery registrable under the Medical Act of 1886. Exemption from Examination in General Surgery and Pathology is granted to candidates who have passed the Examination in Surgery of the Examining Board in England or the corresponding Examinations of the Colleges and University above mentioned. The fee for the diploma is 20 guineas, and is payable as follows:—Preliminary Science Examination, for each admission to Part I., £3 3s.; Part II., £2 2s. First Professional Examination, for each admission to Part I., £4 4s.; Part II., £2 2s.; Second Professional Examination, for each admission to Part I., £4 4s.; Part II., £5 5s. Synopses of examinations and all further information can be obtained from the Secretary, Examination Hall, Queen-square, London, W.C. 1.

Royal College of Surgeons, Edinburgh.—Regulations giving a list of Preliminary Examinations recognised for obtaining the Licence in Dental Surgery, as well as of the subjects of the Professional Examinations, may be obtained from Mr. D. L. Eadie, Clerk to the Royal College of Surgeons, at 49, Lauriston-place, Edinburgh. Candidates must produce certificates of having, subsequently to the date of registration, been engaged for four years in professional studies and of three years' instruction in Mechanical Dentistry from a regis-

tered dental practitioner, except in the case of previously registered medical practitioners, when two years will be considered sufficient. Candidates must also have attended a course of instruction at a University or in an established school of medicine or in a provincial school specially recognised by the College as qualifying for the Diploma in Surgery. In addition they will be required to have attended in a recognised dental hospital, or with teachers recognised by the College, special courses of lectures and instruction in Anatomy and Physiology (Human and Comparative), Surgery, Pathology, Materia Medica, Dental Histology, and Practical Dental Mechanics and Metallurgy; two years' attendance at a dental hospital or the dental department of a general hospital recognised by the College. Practical instruction in Mechanical Dentistry from a registered Dentist, or in the Mechanical Department of a recognised Dental Hospital and School, for three years. Candidates who have passed the First and Second Examinations for the Triple Qualification will be exempt from the First Dental Examination, and will have the advantage of being admissible either to the Final Dental Examination or to the subsequent Examination for the Triple Qualification, or to both. But the First Dental Examination will not be held as equivalent to the First and Second Triple Examinations, and will admit to the Final Dental Examination only. Candidates who are Licentiates of this College or who may be registered medical practitioners will be required to produce certificates of attendance on the special subjects only and will be examined in these only for the dental diploma. First Professional Examination: The candidate must have attended the required courses. The examination embraces (1) Chemistry and Physics; and (2) Anatomy and Physiology. The fee is £5 5s. for the complete examination, and £3 3s. is payable for each division. In all cases of rejected candidates the fee for re-entry is £3 3s. Second Examination: The candidate must have attended the remaining courses of the curriculum, must produce certificates showing that he is 21 years of age, and must pay a fee of £10 10s., for re-entry £5 5s. The examination embraces (1) Surgery and Medicine; and (2) the special subjects of Dental Anatomy and Physiology, Dental Surgery and Pathology, Dental Materia Medica, Dental Mechanics and Dental Metallurgy, with a practical as well as the written and oral examinations in the subjects of Dental and Oral Surgery, Pathology, and Mechanics. The candidate will be tested in the Treatment of Dental Diseases, in Operative Dentistry, the Administration of Anaesthetics, Orthodontics, and in Prosthetic and Mechanical Dentistry. Candidates who claim exemption from the First Dental Examination on the ground of having passed the First and Second Triple Qualification Examinations or other recognised examinations will, before being admitted to the Second Dental Examination, be required to pay the total fee of £15 15s. payable for the dental diploma. Fees and schedules must be lodged with the Clerk not later than one week before the examination.

Higher Dental Diploma.—The College grants a Higher Dental Diploma which is registrable in the Dentists Register as an additional qualification. Every candidate for the Higher Dental Diploma shall produce evidence that he has been engaged in the study or practice of his profession as a Registered Dentist for at least one year subsequent to his having obtained the Licence in Dental Surgery of the College, or a Licence or Qualification in Dental Surgery specially recognised by the College. Particulars as to the examinations can be obtained from Mr. D. L. Eadie, Clerk to the Royal College of Surgeons, 49, Lauriston Place, Edinburgh. The fee payable by Licentiates of the College is £15 15s. For all other candidates £21. A fee of £10 10s. is retained for examination expenses in the case of referred candidates.

The examination embraces the following branches of Dental Science and practice: Dental Surgery, Anatomy, Pathology and Bacteriology, Prosthesis, Anaesthesia, and Dental Radiology. The examination will be clinical and practical as well as written and oral. Candidates will be expected to show a high degree of knowledge and skill.

Royal Faculty of Physicians and Surgeons of Glasgow.—The regulations as to certificates, curriculum, number, and subjects of examinations, fees, &c., are in effect similar to those of the Royal College of Surgeons of Edinburgh, but embrace Dental Bacteriology. Candidates can enter for the First Examination in three divisions, the first embracing

Physics and Chemistry, the second Dental Metallurgy and Dental Mechanics, and the third Anatomy and Physiology. The examination in Dental Mechanics is practical; and there is at the Final Examination an examination in Practical Dentistry conducted in a dental hospital. Copies of regulations, &c., to be obtained from Mr. Walter Hurst, Registrar, Faculty Hall, 242, St. Vincent-street, Glasgow.

Royal College of Surgeons in Ireland.—Candidates for the Licence in Dental Surgery are required to pass two professional examinations. Before the First Examination the candidate must produce evidence of having attended courses in Theoretical and Practical Chemistry, including Metallurgy and Physics, at a recognised institution; of having been registered as a medical or dental student by the General Medical Council; and of having attended courses of instruction in the following subjects at a recognised school of medicine: (a) Anatomy Lectures; (b) Dissections with Demonstrations; (c) Physiology, including Dental Physiology; (d) Practical Physiology and Histology, including Dental Physiology and Histology, Human and Comparative. Before the Final Dental Examination the candidate must have been engaged during a period of two years in acquiring a practical familiarity with the details of Mechanical Dentistry under the instruction of a registered dentist, or under the direction of the superintendent of the Mechanical Department of a recognised Dental Hospital, and have attended, at institutions recognised by the College for the purpose, the following courses of instruction: (a) Dental Surgery and Pathology, Orthodontia, and the Materia Medica and Therapeutics applicable to Dental Surgery. Lectures. Two courses. (b) Dental Mechanics. Lectures. Two courses. (c) Dental Anatomy. Lectures. One course. (d) The practice of a Dental Hospital, or of the Dental Department of a General Hospital. Two years. He must also have attended Clinical instructions at a recognised General Hospital during the ordinary teaching sessions (nine months), and have been engaged during four years in the acquirement of professional knowledge subsequently to the date of registration as a medical or dental student. One year's bona-fide apprenticeship with a registered dental practitioner, after being registered as a medical or dental student, may be counted as one of the four years of professional study. He must be 21 years of age.

In the First Dental Examination candidates will be examined in (A) Physics and Chemistry, including Practical Chemistry and Metallurgy. (B) Anatomy, Physiology, and Histology—General and Dental. All the subjects may be passed at the same time, or they may be passed in two groups, (A) and (B). The examination is partly written, partly *visu voce*, and partly practical.

In the Final Dental Examination candidates will be examined in General Pathology, Medicine, and Surgery; Dental Surgery, and Dental Pathology, with the Materia Medica and Therapeutics applicable to Dental Surgery; Dental Mechanics and Metallurgy; Orthodontia. Candidates must pass in all the subjects at one examination. The examination is partly written, partly *visu voce*, and partly practical, and includes the examination of patients and the performance of dental operations. Candidates are required to provide their own instruments and gold for filling. The First Dental Examination will commence on the first Mondays in the months of February, May, and November. The Final Dental Examination will commence on the second Mondays in the months of February, May, and November. The total fee for the Diploma in Dental Surgery is 20 guineas. Candidates must pay the fees for examinations from which they are exempted, unless when such exemptions have been granted in virtue of examinations passed before the Conjoint Board in Ireland.

University of Birmingham.—The teaching of Dentistry is undertaken by the University acting in association with the Birmingham Dental Hospital and the Birmingham Clinical Board. The instruction at the Dental Hospital is carried out under the direction of the University Dental Clinical Board, so that students may fully qualify themselves for the Dental Diploma (L.D.S.) of this and other universities and licensing bodies. There is a special and well-equipped Dental Museum and Laboratory. An Entrance Exhibition, value £37 10s. is awarded annually at the commencement of the winter session. The following are the regulations for Degrees in Dentistry:—1. The degrees conferred by the University are those of Bachelor and Master of Dental Surgery

(B.D.S. and M.D.S.). 2. All candidates for these degrees must pass the same Matriculation Examination as that required from candidates for Medical Degrees. 3. The degree of Bachelor of Dental Surgery is not conferred upon any candidate who has not obtained a Licence in Dental Surgery. The candidate is not eligible for the degree until a period of 12 months has elapsed from the passing of his examination for the Licence in Dental Surgery. Of this period at least six months must be spent in the dental department of a general hospital approved by the University. 4. A. In addition to the Licence in Dental Surgery the candidate must produce evidence that he has attended the courses required by medical students of the University in the following subjects and passed the Examinations held in the same for Medical and Surgical Degrees: (a) Chemistry and Practical Chemistry, (b) Physics and Practical Physics, (c) Elementary Biology, (d) Anatomy and Practical Anatomy, and (e) Physiology and Practical Physiology. B. That he has passed the class examinations in: (f) One Special Course of Lectures on Medicine, (g) One Special Course of Lectures on Surgery, and (h) Pathology and Bacteriology. C. That he has attended courses and passed the class examinations in: (k) Dental Histology and Patho-Histology, (l) Comparative Dental Anatomy, and (m) Dental Surgery and Prosthetic Dentistry. D. That he has received instruction in the Clinical Examination of living cases at the dental department of a general hospital for a period of not less than six months. 5. The Final Examination will deal with the subjects in Classes C and D. 6. On the expiration of 12 months from the date of passing the Examination for the Degree of Bachelor of Dental Surgery, the candidate will be eligible for that of Master of Dental Surgery. 7. For this degree candidates will be required to submit a thesis containing original work and investigations in some subject connected with Dentistry, which thesis shall be submitted to examiners to be nominated by the Dental Advisory Board.

University of Bristol.—Candidates for the degree of Bachelor of Dental Surgery must be not less than 21 years of age and shall have pursued the courses prescribed by University regulations during not less than five years, of which three shall have been passed in the University, and shall have been registered as dental students by the General Medical Council. All candidates for the degree of B.D.S. are required to satisfy the examiners in the several subjects of four examinations. The First Examination: The subjects are Chemistry, Physics, and Zoology, and the curriculum extends over one year.* The Second Examination: The subjects are Dental Mechanics, Dental Metallurgy, and Dental Materia Medica, and the candidate shall produce evidence of having served for two years an approved pupilage in Dental Mechanics. The Third Examination: The subjects are Anatomy, Physiology, and Histology, Dental Anatomy, and Dental Histology. The Final Examination: The subjects are Medicine and Surgery, Dental Surgery (including Prosthetics), Operative Dental Surgery, and Dental Bacteriology. Degree of Master of Dental Surgery: Candidates shall be Bachelors of the University, shall present a Dissertation on some subject of Dental Surgery to be approved by the Examiners, and pass an examination in Dental Surgery. Diploma in Dental Surgery: Candidates need not be undergraduates, but shall be registered dental students before being admitted to any professional examination; the curriculum extends over four years. A two years' pupilage in Mechanical Dentistry is required, and four examinations must be passed, the subjects of which differ only from those of the B.D.S. in that Zoology is not required for the First Examination, and Medicine is not required for the Final Examination. Candidates who are already registered medical practitioners shall be further exempted from study and examination in Physics and Chemistry, Anatomy, Physiology and Histology, Medicine, and General Surgery.

University of Durham.—Every candidate for the Licence in Dental Surgery must be registered as a dental student. There are four Examinations. The subjects are:—*First*: (a) Chemistry; and (b) Physics. *Second*: (a) Dental Mechanics, Theoretical and Practical; (b) Dental Metallurgy.

Third: (a) Anatomy; (b) Physiology and Histology; (c) Dental Anatomy and Dental Histology; and (d) Dental Materia Medica. *Final*: (a) Surgery; (b) Dental Surgery, including Prosthetics and Orthodontia; (c) Operative Dental Surgery, Practical Examination; and (d) Dental Pathology and Bacteriology. A candidate before presenting himself for examination is required to furnish certificates of instruction in the following subjects, attended after registration as a dental student at recognised Colleges or Schools:—*First Examination*: Chemistry and Physics. *Second Examination*: Dental Mechanics and Dental Metallurgy. *Third Examination*: Anatomy, with Dissections; Physiology; Histology; Dental Anatomy and Physiology; Dental Histology; and Dental Materia Medica. *Final Examination*: Dental Hospital Practice (two years); General Hospital Practice (nine months); Medicine Lectures (two terms); Surgery Lectures (two terms); Dental Surgery and Pathology (a course of not less than 20 lectures); Dental Bacteriology (three terms); Operative Dental Surgery (not less than 12 lectures); and Anæsthetics (a course of not less than one month).

Before admission to the Final Examination each candidate must furnish evidence (1) of having attained the age of 21 years; (2) of having undergone a three years' pupilage in Mechanical Dentistry with a registered dentist; and (3) of having been engaged in professional study for at least four years subsequent to registration as a dental student. The examinations will be held concurrently with the medical examinations, and the fees payable by candidates are as follows: First Examination, £2 10s.; Second Examination, £2 10s.; Third Examination, £3 10s.; Final Examination, £3 10s.; fee for Licence, £3; total, £15. For re-examination: First Examination, £1 10s.; Second Examination, £2; Third Examination, £2 (in one part only, £1); Fourth Examination, £2. The practical examinations in dentistry will be conducted at the Newcastle Dental Hospital.

University of Leeds.—The degrees in Dental Surgery are Bachelor of Dental Surgery (B.Ch.D.) and Master of Dental Surgery (M.Ch.D.). All candidates for the degree of Bachelor of Dental Surgery shall be required to have passed the Matriculation Examination, to have pursued thereafter approved courses of study for not less than five academic years, two of such years at least having been passed in the University subsequently to the date of passing Parts I. and II. of the First Examination, and to have completed such period of pupilage or hospital attendance, or both, as may be prescribed by the regulations of the University. No candidate will be admitted to the degree who has not attained the age of 21 years on the day of graduation. The classes in the Department of Dentistry begin on Oct. 1st. The instruction in the Preliminary subjects of Chemistry, Physics, and Biology are given at the University in College-road. The classes in the other subjects and the systematic courses in Dental subjects are held in the School of Medicine of the University in Thoresby Place. The clinical instruction is given in the Dental Department of the Leeds Public Dispensary, which is affiliated with the University and recognised by the Royal College of Surgeons. Applications for the prospectus should be made to the Dean of the Faculty of Medicine.

University of Liverpool (Liverpool Dental Hospital Clinical School and School of Dental Surgery).—The University grants a Licence in Dental Surgery (L.D.S.) and degrees in Dental Surgery (B.D.S. and M.D.S.). The courses of systematic instruction are given in the University buildings, five minutes' walk from the Dental Hospital. The two institutions are now closely associated, and the management of the curriculum is in the hands of the Board of Dental Studies. The Dental Hospital, covering a site of 672 square yards, is equipped in each department with every modern accessory and receives constant additions. The laboratory is in charge of a skilled dental mechanic under the supervision of the Director of Dental Education and Dental Staff, and students are able to undertake at the hospital the whole of their training in Mechanical Dentistry. The times of the lectures at the University are arranged to meet the convenience of students, thus allowing the maximum time for attendance upon Dental Hospital practice. Fees: The composition fees are as follows: Licence course (L.D.S.): Composition fee £58 10s., for the course of other licensing bodies £61 10s., payable in two equal instalments, the first on entry, the second 12 months

* Candidates who have passed the Higher School Certificate approved by the Board of Education in these subjects will not be required to sit for the first examination for either the B.D.S. or the L.D.S., and will be regarded as having completed one year of study.

later. Two years' instruction in Mechanical Dentistry (pupilage) and two years' Dental Hospital Practice (combined), £100, or in two instalments of £52 10s. each. Degree course (B.D.S.): £67 10s. for all lectures (including Chemistry, Physics, and Zoology) in three instalments. Two years' dental hospital, £21; general hospital practice, £10 10s.; three years' mechanical instruction (pupilage), £105. The fees for tuition have now been increased by one-third. Further information may be had from the Director of Dental Education, Mr. W. H. Gilmour.

University of Manchester.—In the University of Manchester the Dental Department forms an integral part of the Faculty of Medicine. This contains a series of laboratories, lecture rooms, and museums which will bear comparison with those of any otherschool in the kingdom, and the fullest opportunities for study are offered to students preparing for any of the professional examinations. Instruction adapted to the requirements of students preparing for the B.D.S. Degree and the Dental Diplomas of the University, the Royal College of Surgeons of England, and of other licensing bodies is given during the Winter and Summer Sessions both at the University and at the Dental Hospital of Manchester adjoining the University. The required general hospital practice is taken at the Manchester Royal Infirmary. Women students are admitted to the classes in the Dental Department, and for them common rooms are provided. The composition fee for candidates for the University degree of Bachelor of Dental Surgery is 90 guineas, payable in two equal instalments at the beginning of the first and third years of studentship. The composition fee for candidates for the University Diploma in Dentistry is 80 guineas, payable in two equal instalments at the beginning of the first and third years of studentship. The composition fee for candidates for the L.D.S. of England is 90 guineas, payable in two equal instalments at the beginning of the first and third years of studentship. Students who have already served their apprenticeship with a private practitioner, and who propose to complete the final portion of their attendance at the University and at an approved dental hospital, will be required to pay the composition fee in two equal instalments at the commencement of the first and second years of studentship. The composition fee does not include the hospital fees, the examination fees, nor the fee for the conferment of the degree or the diploma.

National University of Ireland.—This University grants the degrees of Bachelor of Dental Surgery and a degree of Master of Dental Surgery. A student may not be admitted to the Degree of Bachelor of Dental Surgery unless a period of not less than four years shall have elapsed from the date of his matriculation, during which period he must have pursued an approved course of study of not less than nine terms. For the degree of Bachelor of Dental Surgery candidates must pass four examinations, the first two being the same as those for the first and second examination in Medicine. The subjects of the third examination are Dental and Practical Pathology, Dental Surgery and Dental Medicine, the subjects of the fourth being Dental Surgery and Pathology, Dental Mechanics, Operative Dentistry, Orthodontia, and Dental Materia Medica. A candidate for the degree of B.D.S. must produce evidence of having been engaged during a period of two years in acquiring a practical familiarity with the details of Mechanical Dentistry under the instruction of a registered dentist, or under professional direction in the mechanical department of a dental hospital approved by the University. A portion of or the entire period may be served before commencing study for the degree of B.D.S., but no portion so taken prior to commencement of study shall count as part of the four years of Dental Study. The degree of Master of Dental Surgery will not be granted until three years after the B.D.S. has been obtained.

Queen's University of Belfast.—At the beginning of next session a Department of Dentistry will be opened, and in due course the University expects to confer a Licentiate in Dental Surgery, a Bachelor of Dental Surgery, and a Master of Dental Surgery. Lecturers have been appointed in Dental Surgery, Dental Mechanics, Dental Metallurgy and Materia Medica, and Orthodontia.

University of Melbourne.—Degrees of Bachelor (B.D.Sc.) and Doctor of Dental Science (D.D.Sc.) are granted. Candidates for the former are required subsequently to matricula-

tion (which must include physics) to take a four years' course of study and to pass four examinations. They shall be apprenticed for not less than three years with a registered dentist in some part of the British Empire. Fee for the four years £100, payable in four equal annual instalments. Annual examination fee £5 5s. Candidates for the degree of Doctor must be Bachelors of Dental Science of at least two years' standing. The examination is partly written and partly oral. A thesis may be submitted.

University of Sydney.—A degree in Dental Surgery (B.D.S.) is granted after a four years' course following matriculation. A graduate in medicine is required to devote four terms to dental study before sitting for the degree of B.D.S. and a licentiate in dental surgery one additional year.

University of Adelaide.—The four years' course for the B.D.S. is regulated by similar conditions to that for the M.B., B.S. Four examinations are held in November of successive years. The fee for each ordinary examination is £3 3s., and for the degree £5 5s. Fees for the whole course amount to £95 11s.

McGill University, Montreal.—The degree of D.D.S. is granted on a four years' curriculum, the first year being that demanded of students in the Medical Faculty.

University of Toronto.—The degree of D.D.S. is granted on a four years' curriculum. Annual examinations are conducted under the joint auspices of the University and the Royal College of Dental Surgeons of Ontario. Concurrent courses may be run in medicine and dentistry extending over seven years.

University of Malta.—The University grants its diploma in dental surgery after examination to candidates producing evidence of four years' professional study and three years' instruction in mechanical dentistry.

TEACHING INSTITUTIONS IN DENTISTRY.

See also under Universities of Birmingham, Leeds, Liverpool, and Manchester above.

LONDON.

Royal Dental Hospital of London, School of Dental Surgery, Leicester-square.—A school of the University of London, and women are now admitted as students and are eligible for all hospital appointments and school prizes.—The school provides the special dental education required by the Royal College of Surgeons for the Licence in Dental Surgery. The general part of the curriculum may be taken at any general hospital. The hospital is open from 9 A.M. to 5 P.M., there being one staff for the morning and another for the afternoon of each day. Pupils are received for the training in dental mechanics recognised by the curriculum. The demonstrators at the commencement of each session give a course of lectures on Operative Dental Surgery. The six house surgeoncies are held for six months each and are open to all qualified students. The lecturers, in addition to their lectures, give special demonstrations on the Microscopy of Dental Anatomy and Dental Surgery. The lecturer on Dental Mechanics also gives practical demonstrations in the laboratory. There is an Entrance Scholarship in Chemistry and Physics of the value of £50. One Entrance Scholarship in Dental Mechanics and Metallurgy value £25, open to pupils of the Hospital only. One Entrance Scholarship of £25 in Dental Mechanics, open to pupils of private practitioners. The Saunders Scholarship of £20 and Saunders Prize of £5 awarded to second year students. The Storer Bennett Research Scholarship for Scientific Research in any branch of Dental Surgery, value £50, is awarded triennially. The Alfred Woodhouse Scholarship of £35 and the Robert Woodhouse Prize of £10 for Practical Dental Surgery. Prizes and certificates are awarded by the lecturers for the best examinations in the subjects of their respective courses at the end of the summer and winter sessions. Fee for two years' hospital practice required by the curriculum, including lectures, £70 in one payment, or £73 10s. in two yearly instalments. The curriculum requires two years to be passed at a General Hospital; the fee for this is about £63. Both hospitals can be attended simultaneously. For the lectures in Chemistry and Physics for the Preliminary Science Examination £13 13s. The fee for the instruction in Dental Mechanics and the two years' hospital practice required by the curriculum is £200 if paid

in one instalment, or 200 guineas if paid in three equal instalments. The fee for tuition in Dental Mechanics is £70 per annum; for one year's hospital practice £28. The Winter Session opens on Oct. 1st.

University College Hospital Dental School.—Corner of Great Portland and Devonshire-streets, W.—This Hospital and School has recently been thoroughly reorganised, and is now fully equipped with all the most modern appliances. Students are entered as students of University College Hospital, and, as such, attend the classes of Chemistry, Physics, Anatomy, and Physiology in University College, which is a few minutes' walk from the Dental Department in Great Portland-street, hitherto known as the National Dental Hospital. The First Dental School to admit Women Students. Practical courses to comply with the R.C.S. curriculum are held. Clinical Lectures and Demonstrations are given, and each student on entering passes through a preliminary course under a demonstrator. Two Entrance Exhibitions, of the value of £40 and £20, are open for competition. Prizes are open for competition at the end of each course of lectures. Fees are under revision. The Calendar, containing full information as to Lectures, Fees, Prizes, and Subjects for the Entrance Exhibitions may be had on application to the Dean, who attends the Hospital on Tuesday mornings at 10.30.

Guy's Hospital.—The work of the Dental Department begins daily at 9 A.M. both in the extraction rooms and in the conservation room. The Extraction Rooms: A new Dental Out-patient Department has been provided. There is ample accommodation for ordinary extractions and anæsthetic extractions, together with waiting- and retiring-rooms. Patients are admitted between 8.45 and 9.30 A.M., and are seen by the dental surgeon for the day, the staff demonstrator, the dental house surgeon, and the dressers. The Conservation Room is open from 9 A.M. till 5 P.M. It has recently been entirely remodelled and greatly enlarged, giving a floor space of over 6000 square feet. It affords accommodation for about 100 dental chairs, with the necessary equipment of the most modern type, for the use of the Dressers, who, under the supervision of the Staff, perform the various operations of Dental Surgery. The members of the staff attend every morning and afternoon to give demonstrations and otherwise assist students in their work in the Conservation Room and Prosthetic Laboratory. The Probationers' Laboratory is supervised by two of the staff demonstrators, and instruction is given in operative dentistry on a "mannikin" to students during their first three months of clinical study. Students in Dental Prosthetics are received, and a graded, systematic, and full course of instruction, extending over two years, is carried out. Dental students have the opportunity of attending at this hospital the whole course of instruction required by the examining board for the L.D.S. Eng.—viz., two years' studentship in dental prosthetics, the special lectures and practice of the Dental Department, and the general lectures and practice of the Medical School. The fees for these two courses may be paid separately or together, or they may be combined with the fees required to be paid for the course for a medical diploma. Students who enter for a medical as well as a dental diploma are allowed to pursue their study of Dentistry during any period of their medical course most convenient to themselves without further charge. Four Scholarships in Dental Prosthetics of the value of £30 each are offered for competition annually, two in September and two in April, and prizes of the aggregate value of £40 are awarded for general proficiency and for skill in Operative Dentistry. The Newland-Pedley Gold Medal for Operative Dentistry is also awarded annually. A Dental Travelling Scholarship of the value of £100 is awarded every second year. Dental students are eligible for admission to the Residential College and enjoy the privileges of students in the Medical School. Application should be made to the Dean of the Medical School.

London Hospital.—This school is a part of the London Hospital and Medical College, and is fully equipped on the most modern lines and with the latest appliances. It provides a complete curriculum in all subjects for the L.D.S. Diploma, and is admirably adapted for the purpose of teaching. The Conservation Room is well lighted and ventilated and fitted with pump chairs of the latest pattern; the fountain spittoon

at every chair has been specially designed and has attached to it a saliva ejector, hot and cold water, compressed air, gas and electric current, also a swing bracket to carry the students' cabinet. Electric sterilisers are supplied in each department and motor engines where required. The School possesses in addition to the Theatres, Laboratories and Museums in the College, a special Museum of Dental Anatomy and Surgery, Operative Dentistry, Prosthetic and Extraction Rooms, and Laboratories for Practical Dental Metallurgy and Dental Prosthesis. A systematic course of instruction in Dental Prosthesis is arranged for pupils. The up-to-date Laboratory contains every modern apparatus and is in charge of a skilled curator and his assistants. Connected with the Medical College and Dental School are a Library, Athenæum, Clubs' Union, Dining Hall with moderate tariff, Students' Hostel, and an Athletic Ground. For full particulars as to fees and course of study advised apply to the Dean, Professor William Wright, who will be glad to make arrangements for anyone wishing to see the Dental School and Medical College.

London (Royal Free Hospital) School of Medicine for Women.—Full courses are arranged for women students for the study of dentistry, and in preparation for the Licence in Dental Surgery of the Royal College of Surgeons of England, at the London (Royal Free Hospital) School of Medicine for Women, in conjunction with the London Dental Hospital, Leicester-square, and the National Dental Hospital, Great Portland-street, W. The course is arranged as follows: First and second years: Chemistry, Physics, and Dental Mechanics. Third, fourth, and fifth years: Anatomy, Physiology, and Special Dental Courses, Courses in Medicine and Surgery, General Hospital Course, Dental Hospital Course. Bursary: The Council of the School will award annually (until further notice) an "Agnes Guthrie" Bursary of the value of £50 to a student fulfilling the required conditions, who enters for the full dental course. Candidates are required to send in applications on or before July 1st, to the Warden and Secretary, from whom a prospectus of the School and all particulars can be obtained.

PROVINCIAL.

Birmingham Dental Hospital, Great Charles-street.—Dean: Mr. W. T. Madin. The Dental Hospital was founded in 1858, and was recognised by the Royal College of Surgeons in 1880 for the teaching of Dental Students. Having an annual attendance of about 16,000 patients, it affords every advantage for students about to enter the profession to acquire a thorough practical knowledge, as required by the Medical Council. The present Hospital was opened on July 6th, 1905. It has accommodation for 50 students. The equipment is in accordance with the most modern requirements for the efficient teaching and practice of Dental Surgery. The operations performed annually average 35,000, including 5000 gold and other fillings, and many cases of crowns, bridges, porcelain inlays, and regulations. By arrangements with the Birmingham University and with the General and Queen's Hospitals the entire course of Lectures, Hospital Practice, &c., may be completed for an inclusive fee of £96 15s., or including Mechanical Pupilage, £186. Examination fees for L.D.S. Birm., total £18. The instruments and materials necessary for Hospital Practice cost about £35. The Composition Fee for the courses required for the L.D.S. of the University, or any of the Corporations alone, is £60, payable in two annual instalments at the commencement of the first and second years; that for the courses required for the L.D.S. and the Degree in Dentistry of the University is £75; that for the L.D.S. in combination with the M.R.C.S. and L.R.C.P. is £85; and that for the M.B., Ch.B., and B.D.S. is £95. All of these composition fees are payable in two annual instalments at the commencement of the first and second years. Each of these fees covers the cost of the courses given at the University for the qualifications indicated, but does not include fees for Hospital teaching. For two years' dental hospital practice the fee is 20 guineas, payable in two instalments of 10 guineas each at the commencement of the first and second (hospital) years respectively. For two years' mechanical pupilage, 85 guineas, which may be paid in two annual instalments of 50 and 35 guineas respectively; mechanical pupils may join for a probationary period of one month, fee 5 guineas, which is deducted upon payment of the full amount. For

general surgical hospital practice, lectures, and demonstrations: Surgery, two winters, £10 10s. One Entrance Scholarship is offered annually of the value of £37 10s. It is awarded to the student who, entering for the Dental Degree of the University in October, or having entered not earlier than the previous April, shall pass the best examination in the subjects studied during his apprenticeship. Candidates must be under the age of 21 years. Application for admission, together with a certificate of birth, must be sent to the Dean of the Medical Faculty, Mr. William F. Haslam, on or before Oct. 15th.

Leeds University School of Dentistry.—The School of Dentistry is fully equipped to provide training for Dental Students, and affords every opportunity for the student to prepare for any of the Dental Degrees or Diplomas. The Demonstrator of Operative Dental Surgery instructs students during their probationary course. At the completion of this training students have patients allotted to them by the Demonstrator, and have every opportunity of acquiring knowledge from the members of the Staff, two of whom are in attendance each day. The following prizes are awarded:—First year Students, value 2 guineas. Operative Dental Surgery Prize, value 5 guineas. Two prizes in Prosthetic Dentistry: (a) a prize, value 2 guineas, for first-year pupils; (b) a prize, value 5 guineas, open for competition to all Students. Extraction prize, value 2 guineas, open for competition to all Students. A prize in Orthodontics, value 5 guineas, is open to all students. All communications should be addressed to the Warden, School of Dentistry, The University, Leeds.

Dental Hospital of Manchester.—This Hospital is in association for teaching purposes with the University of Manchester and the Royal Infirmary, and is in the centre of a very large population. Courses of study are provided to meet the requirements of the various examining bodies, including those of the University of Manchester for the qualifications L.D.S. and B.D.S., and the L.D.S. of the Royal College of Surgeons of England. Clinical instruction is given by the members of the staff and by the house surgeons and demonstrators, and also by the honorary anaesthetists in the administration of nitrous oxide gas; a special class in anaesthetics is conducted by the clinical tutor in that subject, and a class for instruction in porcelain and gold inlay work by the demonstrator specially appointed for that work.

Ten prizes, varying in value from £2 to £12 12s., are awarded annually.

For the whole course of hospital instruction for the L.D.S. (including two years' mechanical training) the fee is £131 5s., paid in instalments. For the two years' Operative Course only, £26 5s., paid in two instalments. For the whole course of hospital instruction for the B.D.S. degree (including mechanical training), £168, paid in instalments. Additional practice in Dental Mechanics may be taken by pupils who have already received their mechanical training elsewhere, at a fee of £36 15s. for six months.

All the courses of instruction are open to women students.

Copies of the Prospectus will be forwarded on application to Mr. J. Hilditch Mathews, Dean.

Newcastle-upon-Tyne Dental Hospital and School.—This Hospital is centrally situated (within five minutes of the various colleges, infirmary, and railway station); the rooms are well lighted and thoroughly equipped for carrying on the work. Dental surgeons and an anaesthetist attend each morning. A tutorial dental surgeon is also in attendance. The Composition Fee for the special Dental Lectures and Dental Hospital Practice is £45 3s. if paid in one sum, or £46 4s. if paid in two instalments of £23 2s. The Composition Fee for the Lectures at the Colleges of Medicine and Science is 40 guineas; in addition to this there is a library and an athletic fee. Particulars of the fee for General Hospital Practice may be obtained from the Senior House Physician, Royal Victoria Infirmary, Newcastle-upon-Tyne. Medals and Certificates of Merit are granted to students showing certain standards of proficiency in the various classes at the Dental School. The prospectus of the Dental Hospital and School, containing full information, may be obtained from either Mr. J. T. Jameson, 12, Windsor-crescent, Newcastle-upon-Tyne, Dean, or Mr. James Coltman, 13, Ellison-place, Newcastle-upon-Tyne, Vice-Dean.

Devon and Exeter Dental Hospital, 24, Southernhay, West, Exeter.—Established 1880.—The hospital is open on Mondays, Tuesdays, Wednesdays, Thursdays, and Fridays, and patients are admitted between the hours of 9 and 11 A.M. Students attend the practice of the hospital under the control of the medical officers. Honorary treasurer, Mr. J. M. Ackland; secretary, Mr. Albert G. Littlejohn.

SCOTLAND.

The Incorporated Edinburgh Dental Hospital and School.—The Edinburgh Dental Hospital and School is located in a spacious and well-equipped building at 31, Chambers-street and offers special advantages to dental students. The General Courses required for the Dental Diploma may be taken in the Medical School of the Royal Colleges of Physicians and Surgeons or in the University schools. The hospital attendance and clinical instruction are taken at the Royal Infirmary. The University, Medical Schools, and Royal Infirmary are within three minutes' walk of the Dental Hospital. The special courses are taken in the hospital. The Dental Hospital practice, extending over two years, affords a student ample opportunity for a full acquaintance with every branch of dentistry. The hospital admits a limited number of indentured pupils. They receive their instruction in Mechanical Dentistry concurrently with the general and special courses. A premium of 60 guineas is payable with each such pupil. The practice and lectures of the hospital are recognised by, and qualify for, all the Licensing Boards. The cost of the hospital outfit of instruments is included in the Dental Hospital fee of £42. The minimum cost of classes and Diploma for the whole course of dental instruction amounts to £98 17s. Those students who desire to take a Medical and Surgical Diploma in addition to the L.D.S. have in this school admirable facilities for so doing. The triple qualification of the Royal College of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow is recommended. The minimum cost of Professional Education, the Triple Qualification, and the Licence in Dental Surgery amounts to £172 19s. The Higher Dental Diploma (H.D.D.) of the Royal College of Surgeons affords all opportunity of obtaining a higher qualification subsequent to registration. Further particulars can be obtained from the Dean, Mr. W. Guy.

Incorporated Glasgow Dental Hospital, 15, Dalhousie-street, Glasgow.—The School is open to Men and Women Students, and Lectures are given on Dental Surgery, Operative Dental Surgery, Orthodontia, Dental Anatomy and Physiology, Pathology, Dental Histology, Dental Mechanics, Crown and Bridge work, Dental Metallurgy, Dental Bacteriology, and Anaesthetics. Lectures on general subjects required for Dentistry may be taken at the University or at one of the extra-mural schools where special provision is made for Dental Students. Composition fee for two years' Hospital Practice and Lectures special to Dentistry, £40 on entry or in two instalments of £21 each. Fees for Hospital Practice and Dental Lectures may be paid for separately, at a total cost of £43 1s. Full information may be had on application to the Dean.

Glasgow Royal Infirmary (Dental Department).—Mr. W. R. Taylor attends at the Royal Infirmary at 9 A.M. on Wednesdays and other days as arranged. The following course in the curriculum can be taken at St. Mungo's College: Anatomy, six months; Practical Anatomy, nine months; Physiology, six months; Chemistry, six months; Practical Chemistry with Metallurgy, three months; Surgery, six months; Medicine, six months; Materia Medica, three months; Clinical Surgery, six months; Dental Surgery, six months, and attendance for two years on the dental department of the hospital. The attendance on the Dental Clinic is free to students of the hospital.

IRELAND.

Incorporated Dental Hospital of Ireland, Lincoln-place, Dublin.—All Dental Students who have passed their First Dental Examination in the Royal College of Surgeons in Ireland (or an equivalent examination or examinations) are admissible to the Clinical Instruction of the Hospital. In addition to Clinical Instruction and Special Demonstrations, courses of lectures are given at the hospital

on Dental Surgery and Pathology, Mechanical Dentistry, the Administration of Anæsthetics, Orthodontia, Dental Anatomy, and Dental Materia Medica. Practical instruction is also given in Anæsthetics. In addition to the longer courses of hospital attendance, courses of three months' duration will be given to surgeons intending to practise in the Colonies or remote country districts, or in the Army and Navy.

Fees.—Dental Hospital Practice (each year), £18 18s.; Lectures, £5 5s. In addition to the above courses registered dentists who are members of the British Dental Association will usually be permitted to take out a three months' course for a fee of 6 guineas. The course in practical Dental Mechanics can be taken in the Hospital Laboratory. Further particulars can be obtained from the Dean.

DOMINIONS.

The Australian College of Dentistry, in connexion with the Melbourne Dental Hospital, trains candidates for the degrees of B.D.Sc. and D.D.Sc. Melb. Students indentured to the College pay £170 in two instalments of £85 each, or four instalments of £42 10s. The superintendent of the College is Mr. E. S. Fisher, L.D.S. D.D.Sc.

United Dental Hospital of Sydney was established in 1901 to provide facilities for the students attending the University Dental School. The fee payable by University students for the dental practice of the hospital is £6 6s. per annum. The secretary is Mr. H. A. Clarke, F.I.A.A.

The Dental Department of McGill University, Montreal, was opened in 1903 at the request of the Dental Association of the Province of Quebec as a section of the medical faculty. An out-patient clinic in dentistry at the Montreal General Hospital provides the clinical material. Particulars from the Registrar of the Medical Faculty.

The Royal College of Dental Surgeons of Ontario has a school of dentistry in connexion with the University of Toronto. Practical work is carried out in the infirmary and laboratories of the College.

REGISTRABLE COLONIAL AND FOREIGN MEDICAL DEGREES.

UNDER the Medical Act, 1886, a number of medical diplomas granted in British possessions entitle their possessors to be registered without further examination in the Colonial List of the (British) Medical Register. The condition attached to such registration is that the holder of the colonial diploma obtained it when he was not domiciled in the United Kingdom or in the course of a period of not less than five years during the whole of which he resided out of the United Kingdom. Some account of these will be given in a later issue of THE LANCET.

THE M.D. BRUSSELS FOR STRANGERS.

THE examination is arranged in three parts. No conditions of residence are needed; the time required for the three examinations seldom exceeds 10 or 12 days, and candidates who are unable to be so long away from home may take each part separately. The examinations are conducted in English through the medium of an interpreter (without additional charge). They take place on the first Tuesday in November, December, March, and May, and the second Tuesday in June. They are *viva voce*, but candidates may have a written examination by paying an additional fee of £1 for each test. This does not exempt them from the *viva voce* examination. Part I. includes general medicine; *materia medica* and pharmacology; general surgery; and the theory of midwifery. Part II. includes general therapeutics; pathology and morbid anatomy, and the use of the microscope; special therapeutics and medicine of internal diseases; special surgery; and mental diseases. Part III. includes public and private hygiene; medical jurisprudence; clinical medicine; clinical surgery; examination in operative surgery, consisting of some of the usual operations on the dead subject—viz., amputation, ligature of artery, &c.; ophthalmology; examination in midwifery, consisting of obstetrical operation on the mannequin (model of pelvis), examination in regional anatomy with dissection; and bacteriology. The address of the Secretary of the Brussels Medical Graduates' Association is 41, Buckland-crescent, Hampstead, N.W. 3.

Annotations.

"Ne quid nimis."

OUR FOOD FROM THE SEA.

IN his presidential address, delivered before the British Association for the Advancement of Science, at Cardiff, at the opening meeting on August 24th, Professor Wm. A. Herdman took for his subject Oceanography and the Sea Fisheries. His studies in this direction as professor of oceanography in the University of Liverpool are well known, and they bear on the future of the supplies of food from the sea. He pointed out that edible animals of the shore may exist in such abundance that an area of the sea may be more productive of food than a similar area of pasture or crops on land. A Lancashire mussel bed, for example, has been shown to have as many as 16,000 young mussels per square foot, and it is estimated that in the shallow waters of Liverpool Bay there are from 20 to 200 animals of sizes varying from a sandhopper to a plaice on each square metre of the bottom. After giving an interesting history of fisheries Professor Herdman spoke on the vexed question of productivity of the trawling grounds, especially those of the North Sea. The enormous increase of fishing power during the last forty years or so had reduced the number of large plaice, so that the average size of that fish caught in our home waters had become smaller, although the total number of plaice landed had continued to increase up to the year of the outbreak of war. Since then from 1914 to 1919 there has been, as Professor Herdman pointed out, the most gigantic experiment ever made in fishery researches by the closing of fishing grounds forced upon us by marine warfare. The effect is so far uncertain, but there are indications of an increase in fish population in certain areas, possibly owing to this less intensive fishing. There may be a lesson in this fact. The problem is to obtain some approximation to a census or valuation of the sea—of the fishes that form the food of man, of the lower animals of the sea-bottom on which many of the fishes feed, and of the plankton or contents of the upper waters which form the ultimate organised food of the sea—and many attempts have been made towards attaining this desired end. Statistics, however, as to the millions of tons of possible food in a sea area are not quite reliable when the fact is considered, as Professor Herdman explained, that all food-fishes are not equally nourishing to man, and all plankton and bottom invertebrates are not equally nourishing to a fish. A fat summer herring differs in essential constitution from the ordinary white fish, such as the cod, which is almost destitute of fat. The assimilative and synthetic powers of fishes evidently differ. The point is emphasised that on these considerations the biologist requires the assistance of the physiologist and the bio-chemist. Our need, concluded Professor Herdman, is research, more research, and still more research. It is instructive to remember how the question of food-supply has occupied the minds of other scientific workers who have been elected to the distinguished post of president to the Association. We may recall Sir William Crookes's address before the Association at its meeting at Bristol in 1898, when he uttered his famous injunction that we should utilise the nitrogen of the air for fertilising purposes, and so increase the food-supply of the nation. That proposition has materialised, and great machinery is in progress for gaining nitrogen from the air and converting it into nitrate. War stimulated the process, which is now turned to the advantage of peace issues. The subject of fish supplies was referred to also in the address delivered at the Cardiff meeting by Professor J. Stanley Gardiner in the Zoological Section. He said, amongst other interesting things, that the abundance of mackerel is connected with the movements of Atlantic water into the British Channel and the North Sea, movements depending on complex astronomical, chemical,

and physical conditions. Their pabulum, as does ultimately that of all animals, resides in that living matter, which possesses chlorophyll for nutrition, commonly called plant. The plant life of the high seas consists of spores of algae, diatoms, and the like, whose abundance as food depends, in its turn, on the amount of the light of the sun—the ultimate source of all life. The British Association is this year again giving evidence of the significance of the application of pure science to human affairs.

"HOSPITALS ON THE RATES."

THE whole hospital question is an urgent one, and how to deal with it wisely remains the most important medical matter of the moment. In our Parliamentary columns last week we gave in full the clauses of the Ministry of Health (Miscellaneous Provisions) Bill, which deal with the assistance from the rates which Dr. Addison proposes should be made available. A week ago immediate financial aid in respect of arrears of repairs and replacements, accumulated during five years of warfare, seemed terribly urgent. Two successive gifts of a quarter of a million each from the Red Cross organisations left this huge need untouched. The announcement early in the week of the allocation to this purpose of £700,000 from the National Relief Fund will serve to meet pressing liabilities and give a little time in which to look quietly round and study the claims of the voluntary system versus hospital municipalisation. There are some three months before Parliament will return to its deliberations. In the meantime, every medical man and every thoughtful citizen concerned with health problems should read the provisions of Dr. Addison's Bill in conjunction with the Dawson Report. There are possible dangers in the Bill which must be safeguarded. As Clause 11 stands it may conceivably enable public opinion to shelve any proper organisation of medical services by merely patching up the worst holes in the existing structure. Improper use of the power given in the Bill to county councils and county boroughs might lead them to special commitments, antagonistic and detrimental to the carrying out of a larger scheme. It is a matter for serious consideration whether it is wise to confirm councils in these powers until a proper health authority has been set up. The difficulty might be met by limiting the operation of the hospital clauses to one year, thus making it a strictly emergency measure. We feel very strongly that it is not really in the public interest to give such wide powers of control over hospitals to municipal bodies, unless some adequate way of expressing, and maybe of enforcing, its opinion is given to the medical profession. The Dawson Report emphasised the vital importance of a sufficient representation of medical men on the health authority, proposing that the medical advisory council for each area should nominate a certain number of medical men for cooption on the health authority. No one would wish to prevent enlightened municipalities from giving temporary grants to the hospitals within their area, but many people would prefer not to hand over to municipalities the power of building and controlling hospitals until after a general and well-considered policy has been formulated by Parliament.

THE LATE PROFESSOR POLITZER.

WITH Professor Adam Politzer, the report of whose death, at the age of 86, reaches us from Vienna, there has passed away the last of a brilliant group of investigators, scientists, and physicians who collaborated towards the end of the nineteenth century in making Vienna a great focus of medical teaching. Although associated in the faculty with Skoda, Billroth, Kaposi, and Turck, Politzer's clinic formed one of the chief attractions to students from all parts of both hemispheres. More than 7000 English and American doctors have taken special courses with this famous teacher. He was able to address them in their native tongue, and thus his ideas and his methods of research and treatment were easily assimilated. The clinic formed a veritable

school for diseases of the ear, and the most prominent otologists on the continent—for example, Viktor Urbantschitsch, Alexander, Neumann, and the Nobel prize-man Bárány—apart from numerous aurists in the United Kingdom and in the States, owe to Politzer the chief part of their training. A native of German Hungary and of Jewish origin, Adam Politzer early showed signs of an enterprising and original mind, for on his appointment as teacher at the University of Vienna in 1861, at the early age of 26, he had previously published important papers on experimental physiology dealing with the innervation of the muscles of the inner ear and the pressure conditions of the labyrinth; he had already studied physiology with Helmholtz and with Claude-Bernard, acoustics with König in Paris, and pathology with Toynbee in London. "The paw of the lion became visible," said his old teacher, Oppolzer. Politzer's method of air inflation into the drum cavity was first published in 1863; politzerisation with a small "p" now appears in the dictionary. In 1870 Politzer was appointed to the chair of otology in Vienna, which he held for 37 years, and was acknowledged as the greatest teacher of his subject almost throughout that period. His collection of anatomical and pathological specimens now revert to his old clinic, whilst his library has been bequeathed to the University of Vienna. It is given to few medical men to develop a threefold claim to a place in the history of medicine. Professor Politzer himself built up a new science, applied his own inventions and discoveries with the utmost technical skill, and did not scorn to spend many hours in each day for four decades in expounding, demonstrating, and teaching. He founded a great school of otology, and his name will never be forgotten.

Medical Diary.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

LONDON HOSPITAL MEDICAL COLLEGE.

MEDICAL UNIT, in the Clinical Theatre of the London Hospital, E.

MONDAY, August 30th.—2 P.M., Mr. Goulden: Eye Conditions in General Diseases of the Central Nervous System.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, August 30th.—2 P.M., Dr. G. Stewart: Medical Out-patients. 2 P.M., Mr. D. Armour: Operations.

TUESDAY.—10 A.M., Mr. Steadman: Dental Department. 2 P.M., Dr. Burnford: Medical Out-patients.

WEDNESDAY.—2 P.M., Mr. Addison: Operations. 2 P.M., Mr. Gibb: Eye Department.

THURSDAY.—2 P.M., Mr. MacDonald: Surgical Out-patients. 2 P.M., Mr. Sinclair: Orthopaedic Department.

FRIDAY.—2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. 2 P.M., Dr. Burnford: Medical Out-patients.

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients.

Daily.—10 A.M., Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

MALE LOCK HOSPITAL, Dean-street, W.

MONDAY, August 30th, WEDNESDAY, and FRIDAY.—5 P.M., Dr. C. Russ: Demonstration of the Treatment of Gonorrhoea by Electrolysis.

Births, Marriages, and Deaths.

MARRIAGES.

EARP—GOODLIFFE.—On August 18th, at Mansfield-road Baptist Church, Nottingham, John Rosslyn Earp, M.A., M.R.C.S., L.R.C.P., to Kathleen May Goodliffe.

WEBSTER—BENTLEY.—At St. John's Church, Old Trafford, Manchester, on the 14th August, 1920, by Rev. C. S. Jackson, Clement Arthur Webster, M.R.C.S., L.R.C.P., of 216, Upper Chorlton-road, Whalley Range, Manchester, to Doris Anne Marie, elder daughter of Ernest J. Bentley, Esq., of "Waltham," Wood-lane, Timperley.

DEATHS.

LEDINGHAM.—On July 22nd, on s.s. *Mogilov*, Christie William Ledingham, M.D., F.R.C.S. Buried at sea, Gulf of Suez.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Sir Shirley Murphy has been elected Master of the Society of the Apothecaries of London.

Presidential Address

[ABRIDGED]

ON

ANOXÆMIA.

Delivered before the Physiological Section of the British Association for the Advancement of Science

By JOSEPH BARCROFT, C.B.E., M.A., F.R.S.,

PRESIDENT OF THE SECTION AND SENIOR DEMONSTRATOR IN PHYSIOLOGY, CAMBRIDGE UNIVERSITY.

LADIES AND GENTLEMEN,—The sentence which lives in my mind as embodying the problem of anoxæmia comes from the pen of one who has given more concentrated thought to the subject than perhaps any other worker—Dr. J. S. Haldane.¹ It runs, "Anoxæmia not only stops the machine but wrecks the machinery." This phrase puts the matter so clearly that I shall commence by an inquiry as to the limits within which it is true.

Anything like complete anoxæmia stops the machine with almost incredible rapidity. It is true that the breath can be held for a considerable time, but it must be borne in mind that the lungs have a volume of about three litres at any moment, that they normally contain about half a litre of oxygen, and that this will suffice for the body at rest for upwards of two minutes. But get rid of the residual oxygen from the lungs only to the very imperfect extent which is possible by the breathing of some neutral gas, such as nitrogen, and you will find that only with difficulty will you endure half a minute. Yet even such a test gives no real picture of the impotence of the machine—which is the brain—to "carry on" in the absence of oxygen. For, on the one hand, nearly a quarter of a minute elapses before the reduced blood gets to the capillary in the brain, so that the machine has only carried on for the remaining quarter of a minute; on the other hand, the arterial blood under such circumstances is far from being completely reduced—in fact, it has very much the composition of ordinary venous blood, which means that it contains about half its usual quota of oxygen. It seems doubtful whether complete absence of oxygen would not bring the brain to an instantaneous standstill. So convincing are the experimental facts to anyone who has tested them for himself that I will not further labour the power of anoxæmia to stop the machine. I will, however, say a word about the assumption which I have made that the machine in this connexion is the brain.

It cannot be stated too clearly that anoxæmia in the last resort must affect every organ of the body directly. Stoppage of the oxygen supply is known, for instance, to bring the perfused heart to a standstill, to cause cessation of the flow of urine, to produce muscular fatigue, and at last immobility, but from our present standpoint these effects of anoxæmia seem to me to be out of the picture, because the brain is so much the most sensitive to oxygen-want. Therefore, if the problem is the stoppage of the machine due to an insufficient general supply of oxygen, I have little doubt that the machine stops because the brain stops, and here at once I am faced with the question how far is this assumption and how far is it proven fact? I freely answer that research in this field is urgent; at present there is too great an element of assumption, but there is also a certain amount of fact.

ACUTE ANOXÆMIA.

To what extent does acute anoxæmia in a healthy subject wreck the machinery as well as stop the machine? By acute anoxæmia I mean complete or almost complete deprivation of oxygen which, in the matter of time, is too short to prove fatal. It is not easy to obtain quite clear-cut experiments in answer to the above question. No doubt many data might be quoted of men who have recovered from drowning, &c. Such data are complicated by the fact that anoxæmia has only been a factor in their condition; other factors,

No. 5062

such as accumulation of carbonic acid, may also have contributed to it. The remarkable fact about most of them, however, is the slowness of the injury which the machine has suffered. These data, therefore, have a value in so far as they show that a very great degree of anoxæmia, if acute and of short duration, may be experienced with but little wreckage to the machine. They have but little value in showing that such wreckage is due to the anoxæmia, because the anoxæmia has not been the sole disturbance. Of such cases I will quote two.

The first is that of a pupil of my own who received a gunshot wound in the head, to the prejudice of his cerebral circulation. I can give you the most perfect assurance that neither intellectually nor physically has the catastrophe which befell him caused any permanent injury. For the notes of the case I am indebted to Colonel Sir William Hale White.

My pupil fell wounded at 6.50 A.M. on Nov. 20th, 1917. As far as is known, he lay insensible for about two hours. Picked up five hours after the wound, he could not move either upper or lower extremity. Thirty-six hours after the wound he underwent an operation, which showed that the superior sagittal sinus was blocked, happily not by a thrombus, but by being torn and having pieces of the inner table of the skull thrust into it, so that for this period of time the motor areas on both sides down to the face area were asphyxiated, the right being much more affected than the left. Six days after the wound the cerebration was still slow, with typically vacant look.

In the left upper extremity the muscular power was much improved; he could raise his arm to his mouth, but he preferred to be fed. In the right upper extremity there were no movements in the shoulder, elbow, or wrist, but he could flex and extend the fingers weakly. In the left lower extremity there were fair movements of hip and knee; no movements of ankle and toes. In the right lower extremity there were no movements of hip, knee, ankle, or toes.

Six weeks after the wound he first walked, although with difficulty; absolutely the last place in which the paresis remained was in the muscles of the right toes. Four months after the injury these toes were spread out and could not be brought together voluntarily. Gradually this has become less, but even now, two and a half years later, all these muscles are weaker than those on the other side.

Such, then, is the wreckage of the machine caused by 36 hours' blockage of the blood flow through the motor areas of the brain; wreckage enough, but not irreparable.

I pass to the second case. It is that of the child of a well-known professor of physiology and a first authority on the subject of respiration. I am indebted to him for the following notes:—

In this child, a male twin, born about 12 weeks too early, it was noticed about 24 hours after birth that the breathing during sleep was irregular and of a very pronounced Cheyne-Stokes type, six to ten breaths being followed by a pause during which no respiratory movement occurred. Usually the pauses were of 15 to 20 seconds' duration, but occasionally (two to ten times a day) the breathing remained suspended for a prolonged period, extending in some cases to 10 and 15 minutes, and in one accurately observed case even to 25 minutes, interrupted by one single breath and a cry about the middle of the period. The breathing invariably started again before the heart beats ceased.

Cases in which the anoxæmia has been uncomplicated are to be found among those who have been exposed to low atmospheric pressures; for instance, balloonists and aviators. Of these quite a considerable number have suffered from oxygen-want to the extent of being unconscious for short intervals of time. No scientific observer has pushed a general condition of anoxæmia either on himself or on his fellows to the extent of complete unconsciousness. The most severe experiments of this nature are those carried out by Haldane and his colleague. One experiment in particular demands attention.

Dr. Haldane and Dr. Kellas² together spent an hour in a chamber in which the air was reduced to between 320 and 295 mm. It is difficult to say how far they were conscious. Clearly each believed the other to be complete master of his own faculties, but it is evident that Dr. Haldane was not so. I gather that he has no recollection of what took place; that whenever he was consulted about the pressure he gave a stereotyped answer which was the same for all questions; that, even with a little more oxygen present, he was sufficiently himself to wish to investigate the colour of his lips in the glass, but insufficiently himself to be conscious that he was looking into the back and not the front of the mirror. Dr. Kellas, who could make observations, never discovered Dr. Haldane's mental condition, though boxed up with him for an hour, and went on consulting him automatically. A somewhat similar experiment was performed on the other two observers, with results differing only in degree.

Yet the after-effects are summed up in the following sentence: "All four observers suffered somewhat from headache for several hours after these experiments, but there was no nausea or loss of appetite."

Of real importance in this connexion are the results of carbon monoxide poisoning. Of these a large number

might be cited. Those interested will find some very instructive cases described in a volume entitled "The Investigation of Mine Air," by the late Sir C. Le Neve Foster and Dr. Haldane.³ The cases in question were those of a number of officials who went to investigate the mine disaster on Snaefell, in the Isle of Man, in May, 1897. Of the five cases cited all suffered some after-effects, by which I mean that by the time the blood was restored sufficiently to its normal condition for the tissues to get the amount of oxygen which they required, the effects of the asphyxia had not passed off and to this extent the machine suffered.

To sum up, then, what may be said of the permanent damage caused by acute anoxæmia, it seems to me to be as follows: No degree of anoxæmia which produces a less effect than that of complete unconsciousness leaves anything more than the most transient effects; if the anoxæmia be pushed to the point at which the subject is within a measurable distance of death the results may take days or weeks to get over, but only in the case of elderly or unsound persons is the machine wrecked beyond repair.

CHRONIC ANOXÆMIA.

And now to pass to the consideration of what I may call chronic anoxæmia—that is to say, oxygen-want which perhaps is not very great in amount—and I shall have to say something later about the measurement of anoxæmia in units, but which is continued over a long time—weeks, months, or perhaps years. We have to ask ourselves, how far does chronic anoxæmia stop the machinery; how far does it wreck the machine? Here we are faced with a much more difficult problem, for the distinction between stopping the machinery and wrecking the machine tends to disappear. In fact, so indistinct does it become that you may ask yourself, with some degree of justice, does chronic anoxæmia stop the machine in any other way than by wrecking it?

The most obvious instances of men subject to chronic anoxæmia are the dwellers at high altitudes. Now, it is quite clear that in many instances of mountain-dwellers the anoxæmia does not wreck the machine. On what I may call the average healthy man anoxæmia begins to tell at about 18,000 feet. At lower altitudes no doubt he will have some passing trouble, but it seems to me from my own experience that this altitude is a very critical one. Yet there are mining camps at such heights in South America at which the work of life is carried on. Under such circumstances the machine is kept going by a process of compensation. This is in part carried out by a modification in the chemical properties of the blood. It would appear that both the carbonic acid in the blood and the alkali diminish. The result, according to my interpretation of my own observations on the Peak of Teneriffe, which appeared to be confirmed by the experiments in a chamber in Copenhagen⁴ from which the air was partially exhausted, was this: the hydrogen-ion concentration of the blood increased slightly, the respiratory centre worked more actively, and the lung became better ventilated with oxygen, with the natural result that the blood became more oxygenated than it would otherwise have been. The difference which this degree of acclimatisation made was very great. Take as an example one of my colleagues, Dr. Roberts.

On Monte Rosa in his case, as in that of the rest of the party, 15 mm. of oxygen pressure were gained in the lungs. To put the matter another way, the amount of oxygen in our lungs at the summit was what it would otherwise have been 5000 or 6000 feet lower down. No actual analyses of the oxygen in Roberts's arterial blood were made, but from what we now know it seems probable that his blood was about 82 per cent. saturated—that is to say, that for every 100 g. of hæmoglobin in the blood 82 were oxyhæmoglobin and 18 reduced hæmoglobin; had this degree of acclimatisation not taken place his blood would have contained as many as 38 parts of unoxidised hæmoglobin out of every 100, and this would probably have made all the difference between the machine stopping and going on.

The body, then, had fought the anoxæmia and reduced it very much in degree, but at the same time the anoxæmia had in a subtle way done much to stop the powers of the body, for this very acclimatisation is effected at the expense of the ultimate reserve which the body has at its disposal for the purpose of carrying out muscular or other work. The oxygen in the lungs was obtained essentially by breathing at rest as you

would normally do when taking some exercise. Clearly, then, if you are partly out of breath before you commence exercise you cannot undertake so much as you otherwise would do. As a friend of mine, who has, I believe, camped at a higher altitude than any other man, put it to me, "So great was the effort that we thought twice before we turned over in bed."

One of the interesting problems with regard to chronic anoxæmia is its effect upon the mind. The whole train of symptoms of CO poisoning strongly suggests some form of intoxication, and is not dissimilar to that produced by alcoholic excess. Here it may be noted that, as far as isolated nerves are concerned, there is pretty good evidence that alcohol and want of oxygen produce exactly the same effects—i.e., they cause a decrement in the conducting power of the nerve. And herein lies a part of its interest, for pharmacologists of one school, at all events, tell me that the corresponding effects of alcohol are really due to an inhibition of the higher centres of the mind; you can therefore conceive of the mental mechanism of self-control being knocked out either because it has not oxygen enough with which to "carry on," or because it is drugged by some poison as a secondary result of the anoxæmia.

Turning to the results of more chronic anoxæmia. If I were to try to summarise them in a sentence I should say that, just as acute anoxæmia simulates drunkenness, chronic anoxæmia simulates fatigue. Another symptom frequently associated with mental fatigue is irritability. Anyone who has experience of high altitudes knows to his cost that life does not run smoothly at 10,000 feet. If the trouble is not with one's own temper it is with those of one's colleagues; and so it was in many cases of gas-poisoning and in the case of aviators.

TYPES OF ANOXÆMIA.

And now to pass to the consideration of the various types of anoxæmia. Anoxæmia is by derivation want of oxygen in the blood. Suppose you allow your mind to pass to some much more homely substance than oxygen—such, for instance, as milk—and consider the causes which may conspire to deprive your family of milk, three obvious sources of milk deficiency will occur to you at once: (1) There is not enough milk at the dairy; (2) the milk is watered or otherwise adulterated so that the fluid on sale is not really all milk; and (3) the milkman from that particular dairy does not come down your road. These three sources of milk deficiency are typical of the types of oxygen deficiency.

The first is insufficient oxygen dispensed to the blood by the lungs. An example of this type of anoxæmia is mountain-sickness. The characteristic of it is insufficient pressure of oxygen in the blood. In mountain-sickness the insufficiency of pressure in the blood is due to insufficient pressure in the air, for, according to our view at all events, the pressure in the blood will always be less than that in air. But this type of anoxæmia may be due to other causes. The sufferer may be in a normal atmosphere, yet for one reason or another the air may not have access to his whole lung. In such cases, either caused by obstruction, by shallow respiration, or by the presence of fluid in the alveoli, the blood leaving the affected areas will contain considerable quantities of reduced hæmoglobin. This will mix with blood from unaffected areas which is about 95 per cent. saturated. The oxygen will then be shared round equally among the corpuscles of the mixed blood, and if the resultant is only 85-90 per cent. saturated the pressure of oxygen will only be about half the normal, and, as I said, deficiency of oxygen pressure is the characteristic of this type of anoxæmia.

The second type involves no want of oxygen pressure in the arterial blood; it is comparable to the watered milk; the deficiency is really in the quality of the blood and not in the quantity of oxygen to which the blood has access. The most obvious example is anemia, in which from one cause or other the blood contains too low a percentage of hæmoglobin, and because there is too little hæmoglobin to carry the oxygen too little oxygen is carried. Anemia is, however, only one example which might be given of this type of anoxæmia. There may be sufficient hæmoglobin in the blood, but the hæmoglobin may be useless for the purpose of oxygen transport; it may be turned in part into methæmoglobin, as in several diseases—e.g., among workers in the manufacture of some chemicals, and in some forms of dysentery contracted in tropical climates, or it may be monopolised by carbon monoxide, as in mine air.

Thirdly, the blood may have access to sufficient oxygen and may contain sufficient functional hæmoglobin, but owing to transport trouble it may not be circulated in sufficient quantities to the tissues. The quantity of oxygen which reaches the tissue in unit time is too small. Literally, according to the strict derivation of the word "anoxæmia," the third type should perhaps be excluded from the category of conditions covered by that word, but, as the result is oxygen starvation in the tissues, it will be convenient to include it. Indeed, it would be an act of pedantry not to do so, for no form of anoxæmia has any significance apart from the fact that it prevents the tissues from obtaining the supply of oxygen requisite for their metabolic processes.

The obvious types of anoxæmia may therefore be classified in some such scheme as the following, and, as it is difficult to continue the discussion of them without some sort of nomenclature, I am giving a name to each type:—

ANOXÆMIA.

- | | | |
|---|--|---|
| 1. <i>Anoxic Type.</i>
The pressure of oxygen in the blood is too low. The hæmoglobin is not saturated to the normal extent. The blood is dark. Examples: (1) Rare atmospheres; (2) areas of lung partially unventilated; (3) fluid or fibrin on surface of cells. | 2. <i>Anæmic Type.</i>
The quantity of functional hæmoglobin is too small. The oxygen pressure is normal. The blood is normal in colour. Examples: (1) Too little hæmoglobin; (2) CO hæmoglobin; (3) methæmoglobin. | 3. <i>Stagnant Type.</i>
The blood is normal, but is supplied to the tissues in insufficient quantities. Examples: (1) Secondary result of histamine shock; (2) hæmorrhage; (3) back pressure. |
|---|--|---|

Anoxic anoxæmia is essentially a general as opposed to a local condition. Not only is the pressure of oxygen in the blood too low, but the lowness of the pressure and not the deficiency in the quantity is the cause of the symptoms observed. Proof of the above statement is to be found in the researches of most workers who have carried out investigations at low oxygen pressures, and it can now be brought forward in a much more convincing way than formerly that oxygen secretion is, for the time at all events, not a factor to be counted with.

The workers on Pike's Peak, for instance, emphasised the fact that the increase of red blood corpuscles during their residence at 14,000 feet was due to deficient oxygen pressure. No doubt they were right, but the point was rather taken from their argument by their assertion in another part of the paper that the oxygen pressure in their arterial blood was anything up to about 100 mm. of mercury. Let me therefore take my own case, in which the alveolar pressures are known to be an index of the oxygen pressures in the arterial blood. I will compare my condition on two occasions, the point being that on these two occasions the quantities of oxygen united with the hæmoglobin were as nearly as may be the same, whilst the pressures were widely different. As I sit here the hæmoglobin value of my blood is 96-97, which corresponds to an oxygen capacity of 0.178 c.c.m. of O₂ per cubic centimetre of blood. In the oxygen chamber on the last day of my experiment, to which I refer later,³ the oxygen capacity of my blood was 0.201 c.c.m. Assuming the blood to be 95 per cent. saturated now and 84 per cent. saturated then, the actual quantity of oxygen in the blood on the two occasions would be—

Oxygen capacity.	Percentage saturation.	Oxygen content.
0.178	95	0.169
0.201	84	0.169

Here I am in my usual health. In the chamber I vomited, my pulse was 86—it is now 56; my head ached in a most distressing fashion, it was with the utmost difficulty that I could carry out routine gas analyses, and when doing so the only objects which I saw distinctly were those on which my attention was concentrated.

In the anoxic type of anoxæmia there may then be quite a sufficient quantity of oxygen in the blood, but a sufficient quantity does not avail in the face of an insufficient pressure. Indeed, as I shall show presently, the anoxic type of anoxæmia is the most serious. We are therefore confronted with something of a paradox in that the most severe type of anoxæmia is one in which there is not necessarily an insufficient quantity of oxygen in the blood at all. And here let me justify the statement that the anoxic type is the most to be feared. I can justify it on either or both of two grounds. Firstly, of the three types it places the tissues at the greatest disadvantage as regards oxygen supply, and, secondly, it is of the three the least easy type for the organism to circumvent.

Let me dwell for a moment upon the efficiency of the blood as a medium for the supply of oxygen to the tissue in the three types. The goal of respiration is to produce and maintain as high an oxygen pressure in the tissue fluids as possible. For the velocity of any

particular oxidation in the tissues must depend upon the products of the concentrations (active masses) of the material to be oxidised and of the oxygen. Now the concentration of oxygen in the tissue is proportional to its partial pressure, and the highest partial pressure in the tissue must, other things being equal, be the result of that type of anoxæmia in which there is the highest partial pressure in the blood plasma.

It is interesting and not uninteresting to try to calculate the degree to which the tissues are prejudiced by being subjected to various types of anoxæmia. Let us suppose that we have a piece of tissue, muscle for instance, which normally is under the following conditions: (a) One cubic centimetre of blood per minute runs through it. (b) The total oxygen capacity of this blood is 0.188 c.c.m. of oxygen per cubic centimetre of blood. (c) The percentage saturation is 97. (d) The oxygen pressure is 100 mm. (e) The oxygen used is 0.059 c.c.m. (f) The oxygen pressure in the tissues is half of that in the veins, in this case 19 mm.

Compare with this a severe case of anoxic anoxæmia, one in which the blood flow is the same as above, and also the oxygen capacity value of the blood, but in which the oxygen pressure is only 31 mm. and the percentage saturation of the arterial blood 66 per cent. Let us, further, retain the assumption that the oxygen pressure in the tissues is half that in the veins. It is possible to calculate, as indeed has been done by my colleague, Mr. Roughton, what the amount of oxygen leaving the capillaries is. The answer is not 0.059, as in the case of the normal, but 0.026—less than half the normal. So, other things being equal, cutting down the oxygen pressure in the arterial blood to 31 and the percentage saturation to 66 would deprive the tissues of half their oxygen. With this compare an example of the anæmic type. The arterial blood shall have the same total quantity of oxygen as in the anoxic case, but instead of being 66 per cent. saturated it shall contain 66 per cent. of the total hæmoglobin, which shall be normally saturated. The amount of oxygen which would pass to the tissues under these conditions is 0.041 c.c.m.—more than half as much again as from the anoxic blood laden with the same quantity of oxygen.

And thirdly, let us take for comparison a case of stagnant anoxæmia in which the same quantity of oxygen goes to the tissue in the cubic centimetre of blood as in the anoxic and anæmic types. On the assumption which we have made the quantity of oxygen which would leave the blood would be 0.045 c.c.m.

In round numbers, therefore, the prejudice to the tissues may be expressed by the following comparison. In this case both of the oxygen going to the blood and going into the tissues I have called the normal 100. This does not, of course, mean that the two amounts are the same. The former in absolute units is about three times the latter. The figure 100 at the top of each column is merely a standard with which to compare the figures beneath it.

	Oxygen in blood going to vessels of tissue.	Oxygen leaving the blood to supply the tissues.
Normal	100 per cent.	100 per cent.
Anoxæmia		
Anoxic	66	42
Anæmic	66	66
Stagnant	66	75

MEASUREMENT OF ANOXÆMIA.

By what scale are we to measure oxygen-want? Let us take the anoxic type first. There are two scales which might be applied to it; both concern the arterial blood; the one is the oxygen pressure in it, the other is the actual percentage of the hæmoglobin which is oxyhæmoglobin. A third possibility suggests itself—namely, the actual amount of oxygen present, but this would be influenced as much by the anæmic as by the anoxic conditions. Of the two possibilities—that of measuring the pressure, and that of measuring the saturation of the blood with oxygen—the latter is the one which is likely to come into vogue, because it is susceptible of direct measurement.

Two converging lines of work have within the last few years brought us nearer to being able to state the degree of anoxæmia in man in terms of the percentage

saturation of oxygen in his blood. The first, introduced by the American researcher Stadie,⁶ is the method of arterial puncture. The needle of a hypodermic syringe can be put right into the radial artery and arterial blood withdrawn. I am not sure that the operation is less painful than that of dissecting out the radial artery and opening it—and in this matter I speak with experience—but it is less alarming, and it has the great merit that it does not injure the artery.

Another method of determining the percentage saturation of arterial blood has invited the attention of researchers. That method is to deduce the percentage saturation from the composition of the alveolar air. Into the merits of the rival methods for the determination of the oxygen in alveolar air I will not go; the method of Haldane and Priestley will suffice for persons at rest. Granted, then, that a subject has a partial pressure of 50 mm. of oxygen in his alveolar air, what can we infer as regards his arterial blood? A long controversy has raged about whether or no any assumption could be made about the condition of the arterial blood from that of the alveolar air, for it was an article of faith with the school of physiologists which was led by Haldane that when the oxygen pressure in the alveolar air sank the oxygen in the arterial blood did not suffer a corresponding reduction. The experimental evidence at present points in the opposite direction, and unless some further facts are brought to light it may be assumed that the oxygen pressure in the arterial blood of a normal person at rest is some 5 mm. below that in his alveolar air. And having obtained a figure for the pressure of oxygen in the arterial blood, where do we stand as regards the percentage saturation? The relation between the one and the other is known as the oxygen dissociation curve. It differs but slightly in normal individuals, and at different times in the same individual. To infer the percentage saturation from the oxygen pressure no doubt the actual dissociation curve should be determined, but in practice it is doubtful whether as a first approximation this is necessary, for a curve determined as the result of a few observations is unlikely to be much nearer the mark than a standard curve on which 20 or 30 points have been determined. Therefore an approximation can be made for the percentage saturation as follows: In a normal individual take the oxygen in the alveolar air, subtract 5 mm., and lay the result off on the mean dissociation curve for man.

Whether measured directly or indirectly, the answer is a statement of the relative quantities of oxyhæmoglobin and of reduced hæmoglobin in the arterial blood. The important thing is that there should be as little reduced hæmoglobin as possible. The more reduced hæmoglobin there is present the less saturated is the blood, or, as the American authors say, the more unsaturated is the blood. They emphasise the fact that it is the quantity of reduced hæmoglobin that is the index of the anoxic condition. They speak not of the percentage saturation, but of the percentage of unsaturation. A blood which would ordinarily be called 85 per cent. saturated they speak of as 15 per cent. unsaturated.

Anoxic anoxæmia, in many cases of lung affection, should be measured by the direct method of arterial puncture, for the simple reason that the relation between the alveolar air and the arterial blood is quite unknown. Such, for instance, are cases of many lung lesions of pneumonia in which the lung may be functioning only in parts, of pneumothorax, of pleural effusions, of emphysema, of multiple pulmonary embolism, in phases of which the arterial blood has been found experimentally to be unsaturated. In addition to these definite lung lesions, there is another type of case on which great stress has been laid by Haldane, Meakins, and Priestley—namely, cases of shallow respiration.⁷ A thorough investigation of the arterial blood in such cases is urgently necessary. Indeed, in all cases in which it is practicable, the method of arterial puncture is desirable. But in the case of many normal persons—such, for instance, as that of airmen at different altitudes—alveolar-air determinations would give a useful index.

The anæmic type of anoxæmia is gauged by the quantity of oxyhæmoglobin in the blood. In the case of simple anæmias this is measured by the scale in which the normal man counts as 100, and the hæmoglobin in the anæmic individual is expressed as a percentage of this. This method has been standardised carefully by Haldane, and we now know that the man who shows 100 on the scale has an oxygen capacity of 0.185 c.cm. of oxygen for every cubic centimetre of blood. We can, therefore, in cases of carboxyhæmoglobin, or methæmoglobin poisoning, express the absolute amount of oxyhæmoglobin pressure either by stating the oxygen capacity and so getting an absolute measurement, or in relative units by dividing

one hundred times the oxygen capacity by 0.185, and thus getting a figure on the ordinary hæmoglobin metre scale.

MECHANISM OF ANOXÆMIA.

Perhaps the most difficult phase of the discussion is that of how anoxæmia produces its baneful results. In approaching this part of the subject I should like to warn my readers of one general principle, the neglect of which seems to be responsible for a vast dissipation of energy. Before you discuss whether a certain effect is due to cause A or cause B, be clear in your own mind that A and B are mutually exclusive.

Let me take an example and suppose

- (1) That the energy of muscular contraction in the long run depends in some way on the oxidation of sugar;
- (2) That in the absence of an adequate supply of oxygen, the reaction $C_6H_{12}O_6 + 6O_2 = 6CO_2 + 6H_2O$ cannot take place in its entirety;
- (3) That under such circumstances some lactic acid is formed as well as carbonic acid;
- (4) That the hydrogen-ion concentration of the blood rises and the total ventilation increases. On what lines are you to discuss whether the increased ventilation is due to "acidosis," by which is meant in this connexion the increased hydrogen-ion concentration of the blood, or to "anoxæmia"? Clearly not on the lines that it must be due to one or other.

In the above instance anoxæmia and acidosis are, to some extent, dependent variables. I have chosen the above case because measurements have been made throughout which make the various assumptions fairly certain, and tell us pretty clearly in what sort of chain to string up the events, what is cause and what is effect. Clearly it would be ridiculous to start a discussion as to whether the breathlessness was due to "acidosis" or "anoxæmia." Each has its place in the chain of events. But I have heard discussions of whether other phenomena of a more obscure nature were due to oxygen-want or to acidosis. Such discussions tend to no useful end.

Nor is this the only problem with regard to oxygen-want, concerning which my warning is needed. Oxygen-want may act immediately in at least two ways:—

- (1) In virtue of absence of oxygen some oxidation which otherwise might take place does not do so, and therefore something which might otherwise happen may not happen. For instance, it may be conceived that the respiratory centre can only go through the rhythmic changes of its activity as the result of the oxidation of its own substance.
- (2) A deficient supply of oxygen may produce, not the negation of a chemical action, but an altered chemical action which in its turn produces toxic products that have a secondary effect on such an organism as the respiratory centre.

Now these effects are not mutually exclusive. In the same category are many arguments about whether accumulations of carbonic acid act specifically as such or merely produce an effect in virtue of their effect on the hydrogen-ion concentration. Here, again, the two points of view are not, strictly speaking, alternatives, and, in some cases at all events, both actions seem to go on at the same time.

It will be evident that in any balanced action in which CO_2 is produced its accumulation will tend to slow the reaction; but, on the other hand, the same accumulation may very likely raise the hydrogen-ion concentration, and in that way produce an effect.

The relation of oxygen to hæmoglobin seems to furnish a case in point. Carbonic acid is known to reduce the affinity of hæmoglobin for oxygen, and other acids do the same. On analogy, therefore, it might have, and has, been plausibly argued that CO_2 acts in virtue of the change in reaction which it produces. Put into mathematical language, the relation of the percentage saturation of oxygen to the oxygen pressure of the gas dissolved in the hæmoglobin solution is expressed by the equation

$$\frac{y}{100} = \frac{Kx^n}{1 + Kx^n} = \frac{x^n}{L + x^n}$$

where $L = 1/K$, where y is the percentage saturation and x the oxygen pressure. The value of K is the measure of the affinity of oxygen for hæmoglobin; the

less the value of K the less readily do the two substances unite.

Now 1/K has been shown by Laurence J. Henderson,⁸ and independently by Adair, to vary directly with the concentration of CO₂. The value of this constant is, according to Henderson, too great to be a direct effect of the CO₂ on the hæmoglobin, and involves as well the assumption that the hæmoglobin in blood is in four forms—an acid and a salt of reduced hæmoglobin and an acid and a salt of oxyhæmoglobin. The presence of CO₂ alters the balance of these four substances.

It is rather fashionable at present to say that "the whole question of acidosis and anoxæmia is in a hopeless muddle." The "muddle," in so far as it exists, is not, I think, by any means hopeless; but I grant freely enough that we are rather at the commencement than at the end of the subject, that much thought and much research must be given, firstly, in getting accurate data, and, secondly, on relating cause and effect, before the whole subject will seem simple. No effort should be spared to replace indirect by direct measurements. My own inference with regard to changes of the reaction of the blood, based on interpretations of the dissociation curve, should be checked by actual hydrogen-ion measurements, as has been done by Hasselbach and is being done by Donegan and Parsons.⁹ Meakins also is, I think, doing great work by actually testing the assumptions made by Haldane and himself as regards the oxygen in arterial blood.

COMPENSATIONS FOR ANOXÆMIA.

For the anoxic type of anoxæmia two forms of compensation at once suggest themselves. The one is increased hæmoglobin in the blood; the other is increased blood flow through the tissues. To go back to the extreme anoxic case already cited, in which the hæmoglobin was 66 per cent. saturated, let us, firstly, see what can be accomplished by an increase of the hæmoglobin value of the blood. Such an increase takes place, of course, at high altitudes. Let us suppose that the increase is on the same grand scale as the anoxæmia, and that it is sufficient to restore the actual quantity of oxygen in 1 c.cm. of blood to the normal. This, of course, means a rise in the hæmoglobin value of the blood from 100 to 150 on the Gowers's scale. Yet even so great an increase in the hæmoglobin will only increase the oxygen taken up in the capillary from each c.cm. of blood from 0.031 to 0.036 c.cm., and will therefore leave it far short of the 0.06 c.cm. which every cubic centimetre of normal blood was giving to the tissue. So much, then, for increased hæmoglobin. It gives a little, but only a little, respite. Let us turn, therefore, to increased blood flow.

In the stagnant type of anoxæmia the principal change which is seen to take place is an increase in the quantity of hæmoglobin per cubic millimetre of blood.

This increase is secondary to a loss of water in the tissues, the result in some cases, as appears from the work of Dale, Richards, and Laidlaw,¹⁰ of a formation of histamine in the tissues. But, so far as the evidence available at the present time can teach any lesson, that lesson is this: The only way of dealing satisfactorily with the anoxic type of anoxæmia is to abolish it by in some way supplying the blood with oxygen at a pressure sufficient to saturate it to the normal level.

It has been maintained strenuously by the Oxford school of physiologists that Nature actually did this; that when the partial pressure in the air-cells of the lung was low the cellular covering of that organ could clutch at the oxygen and force it into the blood at an unnatural pressure, creating a sort of forced draught. This theory, as a theory, has much to recommend it. I am sorry to say, however, that I cannot agree with it on the present evidence. I will only make a passing allusion to the experiment which I performed in order to test the theory, living for six days in a glass respiration chamber in which the partial pressure of oxygen was gradually reduced until it was at its lowest—about 45 mm. Such a pressure, if the lung was incapable of creating what I have termed a forced draught, would mean an oxygen pressure of 38–40 mm. of mercury in the blood, a change sufficient to make the arterial blood

quite dark in colour, whereas, did any considerable forced draught exist, the blood in the arteries would be quite bright in colour. Could we but see the blood in the arteries, its appearance alone would almost give the answer as to whether or no oxygen was forced, or, in technical language, secreted, through the lung wall. And, of course, we could see the blood in the arteries by the simple process of cutting one of them open and shedding a little into a closed glass tube. To the surgeon this is not a difficult matter, and it was, of course, done. The event showed that the blood was dark, and the most careful analyses failed to discover any evidence that the body can force oxygen into the blood in order to compensate for a deficiency of that gas in the air.

Yet the body is not quite powerless. It can, by breathing more deeply, by increasing the ventilation of the lungs, bring the pressure of oxygen in the air-cells closer to that in the atmosphere breathed than would otherwise be the case. I said just now that the oxygen in my lungs dropped to a minimal pressure of 45 mm.; but it did not remain at that level. When I bestirred myself a little it rose, as the result of increased ventilation of the lung, to 56 mm., and at one time, when I was breathing through valves, it reached 68 mm. Nature will do something, but what Nature does not do should be done by artifice. Exploration of the condition of the arterial blood is only in its infancy, yet many cases have been recorded in which in illness the arterial blood has lacked oxygen as much as or more than my own did in the respiration chamber when I was lying on the last day, with occasional vomiting, racked with headache, and at times able to see clearly only as an effort of concentration. A sick man, if his blood is as anoxic as mine was, cannot be expected to fare better as the result, and so he may be expected to have all my troubles in addition to the graver ones which are, perhaps, attributable to some toxic cause. Can he be spared the anoxæmia? The result of our calculations, so far, points to the fact that the efficient way of combating the anoxic condition is to give oxygen. During the war it was given with success in the field in cases of gas-poisoning, and also special wards were formed on a small scale in this country in which the level of oxygen in the atmosphere was kept up to about 40 per cent., with great benefit to a large percentage of the cases. The practice then inaugurated is being tested at Guy's Hospital by Dr. Hunt, who administered the treatment during the war.

Nor are the advantages of oxygen respiration confined to pathological cases. One of the most direct victims of anoxic anoxæmia is the airman who flies at great heights. Everything in this paper tends to show that to counteract the loss of oxygen which he sustains at high altitudes there is but one policy—namely, to provide him with an oxygen equipment which is at once as light and as efficient as possible—a consummation for which Haldane has striven unremittingly. And here I come to the personal note on which I should like to conclude. In the pages which I have read views have been expressed which differ from those which he holds in matters of detail—perhaps in matters of important detail. But Haldane's teaching transcends mere detail. He has always taught that the physiology of to-day is the medicine of to-morrow. The more gladly, therefore, do I take this opportunity of saying how much I owe, and how much I think medicine owes and will owe, to the inspiration of Haldane's teaching.

ON THE
INVESTIGATION OF GASTRIC FUNCTION
BY MEANS OF THE FRACTIONAL
TEST-MEAL.¹

By JOHN A. RYLE, M.D. LOND., M.R.C.P.,
ASSISTANT PHYSICIAN TO GUY'S HOSPITAL.

IN 1914 Rehffuss described a method of obtaining a continued record of the digestive functions of the stomach with the aid of a small-bore rubber tube, having attached to its lower extremity a perforated metal bulb, through which samples of a test-meal were withdrawn at intervals until the stomach was found to be empty. Analyses of the free hydrochloric and total acidity were made on the samples withdrawn and the results were plotted as a curve. The method has many obvious advantages over the old one-hour test-meal.

Together with his co-workers—Hawk, Fowler, Bergeim, and Clarke—Rehffuss published several accounts of the findings obtained both in healthy subjects and in sufferers from various gastric disturbances. Crohn and Reiss have also published observations mainly on hospital patients and having particular reference to the action of acid, antacid, and other drugs on the secretory cycle.

For some reason, however, the fractional method of gastric analysis does not appear to have been widely adopted in this country.

At the beginning of the present year the writer started to review the method both as a means of studying normal gastric physiology and as an aid to clinical diagnosis. Investigations on an extended scale are now in progress, but the results up to date have been so instructive that it seemed desirable to publish a brief account of the method and to forecast some of its possible applications, if only with a view to obtaining for it a wider recognition and trial. With the aid of a Rehffuss's or Einhorn's tube it has become possible to repeat on the healthy human subject a number of the historical animal experiments of Pavlov, and under circumstances far less troublesome and abnormal, while in clinical inquiries the information obtained may be so abundant that, in comparison, the worth of the one-hour test would appear to be greatly diminished. The writer has been able to confirm many of the findings of Rehffuss and to add a few additional observations to those already on record.

The present report consists of: (1) An abridged account of the technique. (2) Reproductions of specimen charts illustrating (a) physiological, (b) pathological phenomena. (3) A summary of the advantages of the fractional method of gastric analysis.

Technique.

The tube employed has been a rubber one, equal to a No. 6 or 8 soft catheter. Attached to the lower end is a small oval brass bulb containing numerous perforations. This is swallowed by the patient and the tube is rapidly "paid out." With explanation and kindly encouragement there should be no failures. Both in the descent of the tube and during withdrawal there is a tendency for the bulb to stick at the constriction corresponding with the cricoid. In withdrawal no force should be employed, but the patient should exert slight tension on the tube and swallow. As the wave of relaxation passes over it the bulb slips into the mouth. With the tube in place a specimen of resting juice is withdrawn and the total amount if necessary measured. A Record or all-glass syringe should be used for preference for withdrawing samples. A rack of 10 or 12 numbered test-tubes is at hand. The patient without withdrawing the tube drinks one pint of test-gruel prepared according to a fixed recipe,² and at intervals of quarter of an hour specimens

of about 10 c.cm. in bulk are aspirated. After sedimentation in the tubes has occurred naked-eye observations are made of the food-content and the presence and amount of mucus and bile; the free and total acidity are determined quantitatively by the usual tests; and the time of disappearance of starch is noted by adding iodine to the residue in the tubes.

An average curve in a healthy subject presents the following features. From a resting free acidity varying

CHART 1.

between 0 and 20 (N/10 NaOH), and following an initial fall due to dilution, there is a gradual rise up to 1 1/2 or 2 hours, the maximum seldom exceeding 40 for the free or 60 for the total acidity. The curves run closely parallel. There is a slight drop from 2 1/2 to 2 3/4 hours, at which time emptying is usually complete. The starch disappears in the last or penultimate specimen. There is a tendency for the mucus to increase as the food diminishes. Bile regurgitation may be present in the resting juice, and occurs at some period of the cycle—usually towards the end—in about 50 per cent. of

CHART 2.

healthy males. The criteria of approaching emptying are the withdrawal of frothy specimens of small bulk, the appearance of bile, and the disappearance of starch.

The figures for the acid are lower than those obtained with Ewald's test-meal, probably on account of the elimination of the psychic factor, the oatmeal gruel being somewhat unappetising and demanding no mastication.

Specimen Charts.

Chart 1 was obtained in the writer's case. It may be regarded as an average normal curve; it conforms with the type of curve obtained in upwards of 75 per cent. of healthy males.

Chart 2 shows the result of a milk test-meal of one pint obtained in the writer's case. Note the high-rising total acidity indicating the specific food response; the inverse ratio of free and total acidity after 2 hours possibly indicating acid-protein combination; and the slow rate of emptying—4 hours—probably due to the presence of fat, since skimmed milk in equal bulk emptied in 2 1/2 hours, while a meal of

¹ Based upon a communication made to the meeting of the Association of Physicians at Manchester.

² Mix two tablespoonfuls of breakfast oatmeal with one quart of water. Boil slowly down to one pint. Strain through muslin. Add salt to taste and give warm.

subjective peristaltic sensations and sometimes with audible borborygmi.

Chart 3 shows the result of drinking half a pint of water. Emptying was not complete for 55 minutes, but took place rapidly after the free acid reached 30. Emptying appeared to become active at this degree of acidity in all the writer's tests, the attainment of this point, at whatever phase of the curve it occurs, coinciding with the most active

CHART 3.

CHART 4.

CHART 5.

CHART 6.

CHART 7.

In the pathological series:—

Chart 4 is from a case with history and symptoms strongly suggestive of duodenal ulcer. Note the high acidity of the resting juice, which is very copious, the steep-climbing curve, and the continued secretion. Curves of this character have been very constantly obtained in "duodenal" cases.

Chart 5 is from a case of duodenal ulcer confirmed at operation. In this case a clinical and X ray diagnosis of chronic gall-bladder and appendix was made. The additional diagnosis of ulcer was made on the test-meal result. Note that at one hour the acidity is within normal limits, whereas half an hour later there is definite hyperchlorhydria. Note also the extremely rapid emptying—"duodenal hurry"—the presence of blood in 8 out of 10 specimens, and the continued secretion.

Chart 6 is from a man, aged 51, whose clinical features strongly suggested growth; vomiting was absent, but the test showed very definite pyloric delay. In addition there is achlorhydria and a big disparity between free and total acidity.

Chart 7 is from a case of acne rosacea. In this condition, the association of which with indigestion is well recognised, achlorhydria or marked hypochlorhydria has been very constantly demonstrated.

Summary.

The advantages of the fractional method of gastric analysis may be summarised as follows:—

(1) Its technique is 'extremely simple. Both for patient and operator the manipulations involved are easier and less unpleasant than is the case with the large stomach-tube.

(2) It is probably the best method yet described for investigating and also for demonstrating to students the secretory functions both of the healthy and the unhealthy human stomach. For—

(3) It allows of a graphic presentation of the whole digestive cycle with reference to the free and total acidity, the secretion of pepsin, the secretion of mucus, the regurgitation of bile, and the rate of disappearance of starch and sugar from the examined contents.

(4) It allows of an estimate of the rate of emptying at least as accurate as that obtained by means of radiography and the barium meal.

(5) It allows of qualitative and quantitative investigations of the resting juice and of the post-prandial secretion (when present), and of its cytology and bacteriology, as well as its chemical features.

(6) It avoids the fallacy of a one-hour reading with subsequent or previous abnormal variations.

(7) It makes possible the investigation of certain symptoms, such as "heartburn" and of pain, having special time relationships.

(8) It permits of the study of the local action of drugs taken into the stomach and of reflex secretory effects.

(9) By means of parallel X ray examinations a correlation of chemical and mechanical functions becomes possible.

(10) Owing to the whitish colour of the gruel employed

and the number of specimens withdrawn small quantities of macroscopic blood are much less likely to escape detection than with the older methods.

If necessary investigations can be pursued beyond the pylorus, as, with X ray coöperation, the bulb can easily be passed into the duodenum.

No attempt has been made in this communication to base conclusions on the results thus far obtained, for the inquiry, so far as the writer and his colleagues are concerned, is still in its early stages.

Thanks are due to Dr. A. F. Hurst, who has largely stimulated the investigation and provided numerous cases of interest; to Dr. M. S. Pembrey and Dr. J. H. Ryffel, in whose laboratories at Guy's Hospital the work has been done; to Dr. T. I. Bennett, who is at work on normals and also upon pharmacological effects; and to Mr. M. Maizels and numerous students who have volunteered to act as subjects in order to

Tubes used in fractional gastric analysis (described in text).

help in the establishment of the normal variations.

For the illustrations (Figs. A and B) of the tubes employed the writer is indebted to Messrs. Down Brothers. Fig. B is a modification designed to facilitate swallowing and to avoid the possibility of slight trauma to the gastric mucosa when strong suction is exerted through the metal bulb on an almost empty stomach.

ANTISYPHILITIC PROPHYLAXIS:

AN INVESTIGATION INTO ITS USE, NON-USE, AND MIS-USE.

By G. R. HAMILTON, M.B., CH.M. SYD.,

CLINICAL ASSISTANT TO THE SKIN AND SYPHILIS DEPARTMENTS, LONDON HOSPITAL; CAPTAIN, AUSTRALIAN ARMY MEDICAL CORPS.

IN order to arrive at some figures with regard to the use of venereal disease prophylaxis by men and at some true information as to what, if any, precautions are being taken amongst the class of people who present themselves at one of the ordinary public centres for the free treatment for venereal disease, I have recently collected information from 608 cases who presented themselves at the syphilis clinic at the London Hospital under my chief, Dr. J. H. Sequeira.

Scope of Inquiry.

This report has reference solely to syphilitic infection and to no other venereal disease.

For the most part the men concerned were of the ordinary hospital out-patient class, but there were some more intelligent people amongst them, such as military officers or clerks. The plan adopted was the private questioning of each individual patient, and I have every reason to believe they answered questions truthfully. As far as possible the cases were taken consecutively as they came on certain special days for syphilis. Careful

attention was directed towards accuracy of time of events; what precautions were used, and how used, and whether before, after, or during connexion; how much of the prophylactic agent was used, and whether the patient had had any intoxicating liquor at the time or not.

Many interesting and useful points were elucidated during the questioning.

Many contracted the disease while in France from "licensed houses," and because the houses were "licensed" they all, without exception, believed the women were "clean," and therefore took no precautions at all. This fully endorses what Lieutenant-Colonel E. T. Burke, R.A.M.C., says in his article¹ on "Venereal Disease in War":—

"The licensing of brothels and the medical examination of the inmates possess not the slightest value. This has been fully proved wherever it has been tried. In spite of medical examination it is quite impossible to guarantee that any public woman is free from infection. Regulation gives a false sense of security and makes the authorities directly responsible for any infection that may result."

Some believed that a solution of potassium permanganate, or Condy's, applied by a few moments' douching, and of no matter what strength and how long after the connexion, was sufficient protection. Others believed that the washing of their parts with their own urine, even hours after, was also sufficient protection against venereal disease. Ordinary washing with soap and water soon after connexion was very rarely done. Lysol and other similar drugs were used by a few, even to a strength which resulted in burns. Of those infected after using a rubber sheath, each definitely stated that the sheath broke during connexion. (See below.) The high percentage of those infected during partial or total intoxication by liquor will be referred to later.

Of the 608 cases only 12 had used, in various ways, prophylactic outfits—"packets"—with calomel ointment (33 per cent.). These I have labelled "special" cases in the table of results of inquiry, and will give their details later.

Table of Results of Inquiry.

(1) Took no intoxicating liquor and used no prophylaxis at all	287
(2) Intoxicated	102
(3) Partially intoxicated and used no prophylaxis at all	67
(4) Partially intoxicated and used pot. permang. within 10 minutes of connexion	5
(5) Partially intoxicated, but bathed with own urine within 10 minutes of connexion	8
(6) Used pot. permang. within 10 minutes of connexion	24
(7) Used pot. permang. from 10 minutes to 12 hours after connexion	51
(8) Used soap and water within 10 minutes of connexion	10
(9) Used tap water only within 10 minutes of connexion	14
(10) Bathed penis with own urine within 10 minutes of connexion	16
(11) Used rubber sheath which broke during connexion	5
(12) Used lysol or similar drug within 10 minutes of connexion..	7
(13) "Special" cases (calomel—see below)	12
Total	608

From this table it will be seen that the following information can be extracted:—

Total number of those using no prophylaxis (1, 2, 3)	456, or 75%
Total number of those under influence of liquor (3, 4, 5)	182, or 29.9%
Total number using pot. permang. (4, 6, 7)	80, or 13.2%
Total number bathing in own urine (5, 10)	24, or 3.9%

Details of "Special" Cases.

CASE A.—Four hours after connexion, rubbed half tube of calomel from a packet on to the glans only. Did not rub any into the corona or on the body of penis. Chancre developed on the body $\frac{1}{2}$ inch behind the frenum, where he did not rub any calomel.

CASE B.—Quarter of an hour before connexion injected half tube of nargol into urethra and placed half tube of calomel around corona. Twelve hours after connexion used other half of each tube as before. Chancre developed $\frac{1}{2}$ inch behind frenum on body of penis where he did not rub any calomel.

CASE C.—Had connexion three or four times with the same woman on three or four consecutive days and only used calomel around the last connexion of all. Immediately after the last connexion he washed his penis in water and rubbed on and injected calomel from a military prophylactic outfit, using one whole tube. Chancre developed on glans one month after. Had had other previous recent connexions when he did not use any prophylaxis at all.

CASE D.—Rubbed on quarter tube of calomel immediately before and after connexion, to glans, corona, and body only. Had "wash-out" at military prophylactic tent 10 minutes after. No sign of chancre on penis or scrotum, but his throat was very suspicious. He had post-cervical and epitrochlear adenitis, a macular rash, and condylomata at the anus.

CASE E.—Immediately before connexion used a navy packet. He injected about quarter tube into urethra and placed about quarter tube on glans. After connexion he did the same, using about the same amounts and also washed in Condy's one hour afterwards. He stated that there were no instructions how to use the tube in the packet. The chancre developed on the body side of the corona where he did not rub any calomel.

CASE F.—Half hour after connexion went to a military prophylactic tent where he washed the parts and syringed out his urethra with pot. permanganate and rubbed calomel ointment all over his penis, but using only half a tube. Three days later two sores developed, one on the prepuce and one on the frenum. He had had previous recent connexions when he did not use any prophylaxis at all.

CASE G.—Used nothing before or after the connexion. Three weeks later a sore developed on the glans which he reported to his medical officer, who instructed him to use calomel ointment. He used one whole tube.

CASE H.—Before and after connexion he rubbed on calomel to penis only, from a Canadian Red Cross packet. No chancre developed on his penis, the primary lesion being in his throat.

CASE I.—Two hours after connexion he rubbed on and injected calomel from a military outfit. Owing to not being able to get his prepuce back he was unable to get any ointment there and that is where the chancre developed.

CASE J.—Thirty-six hours after connexion he injected quarter tube of nargol into urethra and placed on quarter tube of calomel around the corona, from a "Dreadnought" outfit. Two weeks later he developed two sores in the corona. He had had previous recent connexion, when he used no prophylaxis at all.

CASE K.—Quarter of an hour after connexion he injected half tube of nargol into urethra and rubbed on half tube of calomel on to penis and scrotum, from a "Dreadnought" outfit. Chancre developed on left inner side of thigh where he did not rub on any calomel ointment.

CASE L.—One hour after connexion he injected quarter tube of calomel into his urethra, and rubbed three-quarters tube on to glans and corona from a military outfit. Chancre developed on middle of body of penis four weeks later, where he had not rubbed on any calomel ointment. Ten days previous to this connexion he had had another, when he did not use any prophylaxis at all.

Discussion of Results of Inquiry.

That 30 per cent. of the cases were under the influence of drink at the time tells its own story. Alcohol not only lowers the resistance, but it is asserted that connexion takes longer when under its influence. Hence there is a longer time for the parts to be in contact, and so the parties are more liable to infection. Also in the rare cases in which prophylactic measures were intended they would probably be omitted if the man were partially intoxicated, and certainly if he were totally intoxicated.

It must be well noted that there was not a single case of infection after using a rubber sheath, except when the sheath had broken actually during connexion. This fact led me to make inquiries from chemists and other shops where sheaths are sold, and from them I learned that an average of 10 gross per week were sold at each. One shop claimed to sell as many as 50 gross per week. These shops were in the central part of London. Granted that many were sold to married people and others to prevent conception, yet this also surely means that one of the best prophylactics we have is the rubber sheath. This means of prophylaxis is also advocated by Professor Gougerot,² who, under the heading of "Venereal Disease Can be Avoided," in his recent report to the Interallied Congress of Social Hygiene, says:—

"..... Before the act grease the parts with calomel ointment or with some such ointment. Put on a substantial rubber sheath which has not already been used"
and in another place:—

"A good sheath, not having been used, is, in every way, the surest means of escaping contagion."

As regards prophylactic outfits—"packets"—only 12 of the 608 cases had used this system and all had in different ways applied the calomel ointment wrongly. Either they had used it only after connexion, or had not rubbed it in over all the parts recommended, or had used it much too late. It is important to note that of the 12, 3 developed extra-genital chancres; 1 used calomel after the chancre had developed; 1 applied calomel only after the last of a series of connexions lasting over several days; 3 had had previous recent connexions when they did not use any prophylaxis at all; 4 developed chancres at sites different from the site where they applied the calomel ointment, and one of these had also had a previous recent connexion, when he had not used any prophylaxis.

Here, again, the evidence points in favour of the efficiency of calomel ointment as a prophylactic against syphilis. From chemists I also asked for information about this ointment, and they stated that though they could not by law offer for sale or advertise the germicidal properties of the ointment, yet they sold quite a quantity to those who asked for it or had it ordered by a medical prescription. Professor Gougerot,² also in the same report, says:—

"..... Smear calomel ointment or in its place some similar ointment and use a sheath"

He also advocates the rubbing in of calomel ointment immediately after connexion.

Data Taken from Recent Military Experience.

The Canadian military authorities³ actually issued 571,180 tubes to an average strength of 277,500 troops in Great Britain from April, 1917, to August, 1919, and their Y.M.C.A. branch in Paris, from November, 1917, to March, 1918, gave out 50,000 preventive tubes to 22,000 men of the Imperial Force who were on leave to Paris between those dates. This means that the number of tubes issued was about double the number of men.

In Paris from June to November, 1918 (five months), with abundant disinfectants given individually to the Anzacs⁶ on leave, the number of infections was only 20, whereas in the five weeks, November–December, when the supply of disinfectants was temporarily cut off, the number of infections was 24. In October, 1918, there were approximately 5000 troops on leave, a large proportion being Anzacs, among whom in that month there were only 3 infections, whereas among the English, who were not nearly so well supplied with disinfectants, there were in that month 42 infections. Also in August to September, 1917, when there

was no issue of disinfectants, over 5000 troops came on leave to Paris and over 1000 of them became infected, whereas in November, 1917, to March, 1918, when over 30,000 came on leave and there was an issue of disinfectants, only 3 per cent. became infected.

From this I would deduce that the prophylactic system was not a failure, but the results show that, if properly carried out, this system was reasonably effective in preventing venereal disease.

More recently still have been published the results of the prophylactic system in use at certain military units at Portsmouth,⁷ where the rate of infection of venereal disease fell to 1.5 per 1000 per annum, and now the town council of Portsmouth is seeking to popularise methods of prevention among the civil population of the borough. At Liverpool military camp in New South Wales⁸ the rate of infection was also greatly diminished by such a system.

Most people, I think, agree that calomel ointment is an almost sure agent if applied correctly, and I want to lay great emphasis on the fact that all "packets" should have proper instructions for use enclosed, especially insisting on the use of both a sheath and calomel ointment at the same time, for, as Lieutenant-Colonel G. Raffan, A.A.M.C.,⁶ points out:—

"Rubber sheaths alone are not safe, they vary in quality and are sometimes very fragile a (calomel) lubricant in addition is desirable."

Had the 5 cases quoted in my table above used calomel ointment as well as the sheath, and had 6 of the 12 "special" cases applied the calomel correctly, most probably they would not have become infected.

Pitfalls and their Avoidance.

It is also necessary to emphasise very strongly, in the instructions, that the influence of alcohol at the time notably increases the risk of infection. The calomel ointment should be rubbed in well, not merely placed on all parts. It is said that calomel is apparently converted into perchloride⁴ within the tissues—hence the need of rubbing it in.

To guard against attempts at self-treatment by infected people with outfits it should be clearly stated in the instructions that the outfits will only prevent and not cure.

These, I think, are the chief points bearing on the figures I have obtained. The above and other instructions as regards other drugs and their method of use have been published many times, but from my figures as regards syphilis it cannot be too well drilled in that alcohol is to be avoided at the time, that calomel ointment must be rubbed in, and that at the same time suitable precautions must be taken against other venereal disease.

Lastly, the importance of early treatment centres cannot be overlooked, especially as such a great percentage become infected when under the influence of liquor and therefore use no prophylaxis at all. Early treatment centres should then be available the moment the man regains his senses.

Lieutenant-Colonel Burke¹ has recently published some extraordinarily good results, and I cannot do better than quote them here:—

Number applying for prophylaxis	894
Number of above who developed symptoms	Nil.
Number of venereal cases admitted	78
Number of these who had had prophylactic treatment	2

Which clearly shows what can be done when prophylaxis is properly carried out.

After all, prophylaxis is only common-sense hygiene; and as Dr. Sequeira very aptly puts it: "It is for the same reason a surgeon washes and disinfects his hands before and after and wears rubber gloves during an operation."

I am greatly indebted to Dr. Sequeira for having allowed me to make these observations.

THE PRINCIPLES UNDERLYING THE STANDARDISATION OF AGGLUTINABLE CULTURES.

With a Note on

THE APPLICATION OF DREYER'S SYSTEM TO
B. PARATYPHOSUS A.

BY A. D. GARDNER, D.M. OXON., F.R.C.S. ENG.

(From the Department of Pathology, University of Oxford, Standards Laboratory.)

IN attempting to form a true estimate of the value of Dreyer's system of standardisation it is important to give separate consideration to its two aspects: (1) The general principles upon which it is based; (2) the particular applications of the principles to serological practice that have been made or proposed. A number of private discussions concerning the use of standardised cultures have made it clear that a statement of general principles is needed if tiresome misunderstandings are to be avoided.

The present article is an attempt to state these principles and their working in general terms without reference to the various published criticisms of Dreyer's method, for these have dealt almost entirely with standardisation in clinical practice. The reader is, however, recommended to peruse Part I. of the Medical Research Committee's Special Report Series, No. 48 (1920), in which certain observations of Drs. W. W. C. Topley, A. C. Imrie, and S. G. Platts seem to conflict with some of the principles here stated.

The Measurement of Agglutinating Power.

The possibility of making some kind of measurement of the agglutinating power of a serum has long been recognised, and the expression of such measurements in figures representing the highest dilution in which complete (or partial) agglutination occurs has become an established practice in bacteriological laboratories all over the civilised world.

The great majority of workers in this sphere have employed living or killed agar cultures of the bacilli for their agglutination tests, and it has been tacitly assumed that 24 hours agar cultures suspended in salt solution form a material so constant in agglutinability that they can be satisfactorily employed as a standard for the measurement of the power of a serum.

I use the word "standard" advisedly, and for this reason: It is axiomatic that no measurement or series of measurements can be made without a standard. Every measurement is a comparison of X with Y, wherein Y is the standard whereby X is measured. If Y be a permanent and constant quantity it can be used as standard for an indefinite series of measurements; but if it be perishable or an un-reproducible quantity it can only be used for the single operation. Measurements of length are only possible if we choose an object of a particular length as our standard and compare with it the articles which we desire to measure. Every man can have his own standard of length, if he will, and make his measurements with it to the highest possible pitch of accuracy. But in such a case John Smith, who has chosen the span of his right hand as his unit, will suffer no little inconvenience when purchasing articles from Dick Robinson, whose custom it is to measure with the cubit. A laborious process of translation will have to be gone through at each transaction. Language is another simple case of standardisation. A word is but the standard sound agreed on by a group of persons for the expression of an idea; and it would clearly be an enormous convenience and saving of time and labour if the whole civilised world could agree to a single set of standards, though this might possibly bring with it, in our present state of civilisation, disadvantages in the realms of history and sentiment heavy enough to outweigh the practical gain.

But to return to our subject, we must be clear as to what has hitherto been the actual standard in agglutination tests. Our custom has been to measure the highest dilution of serum that can bring about a definite change in a suspension of bacteria. Since we are dealing with only two materials, serum and culture, and since the former is being measured, it is clear that the culture is the substance by means of which we are measuring it.

The actual comparison is, of course, not between serum and culture, but between one serum and another serum measured either with the same culture or with another which has been assumed to be of identical agglutinability. The culture is thus our standard, though a standard of a nature slightly different from that of simple standards of length, weight, and so forth.

Just as we have seen that any man may make perfect measurements of length by means of any unit that takes his fancy, so any man can make accurate comparisons of the power of two or more sera by means of any specific bacterial suspension he may chance to make, though his tests must be done all at once and can never be repeated if the bacteria are alive and unfixed, for his standard is perishable. If he has killed and partly fixed his bacteria, in bulk, he has a much better but still imperfect and undurable standard available until it is all used up.

Now the whole of the system of agglutinin measurements in the past has been based on the assumption that all 24-hour cultures of a given bacillus possess a sufficiently constant degree of agglutinability. If this were so they would constitute a satisfactory standard material; but it is not so. Not only do they vary, but they vary profoundly. A strain of the typhoid bacillus may yield one day a culture which reacts with a ten thousandfold dilution of a specific serum, and another day may show no response to the same serum at 1 in 100. This is an extreme case, but variations of smaller though still very considerable amplitude are the rule; so that two successive subcultures of a typical and highly agglutinable strain of, e.g., *B. typhosus*, may differ by 100 or 200 per cent. in their end-titres with a serum.

It may be that future discoveries will enable us to control the exact composition of culture media and all the conditions of bacterial growth in such a way as to ensure the production with certainty of uniform living cultures of constant agglutinability. But this is at present impossible and is quite likely to remain so. The position, then, until recently may be described thus:—

In measuring the agglutinating power of sera bacteriologists have used a method in which the standard is the agglutinability of 24 hours' cultures of strains of the organism in question. Since the results of all measurements of whatever nature can only be expressed as multiples of some unit, a unitary system has had to be adopted here also. It is, however, "camouflaged," so that it appears superficially not to be a unitary system at all.

Let us analyse the expression "titre = 1/1000."

It means that the highest dilution of serum which gave the reaction was 1 part in each 1000 parts of the test mixture (serum and suspension). In other words, the least quantity of serum that reacted was one unit by measurement in every 1000 units by measurement of the mixture. This quantity is really the unit of agglutinating power¹ in this system of measurement. If we measure in cubic centimetres our result can be stated thus. By mixing 1 c.cm. of the serum with 499 c.cm. of diluent we obtain a mixture of such agglutinating power that 0.5 c.cm. of it will just react with 0.5 c.cm. of the suspension. This 1 c.cm. of final dilution may therefore be said to be 1 unit strong. The full-strength serum is, then, clearly 1000 units strong. But it is, in truth, only for the particular suspension in use that this statement holds good. With other suspensions the end-dilution and therefore the estimated strength of the serum would not be the same. Perhaps it is for this reason that the expression in dilution has been retained and an expression in units rejected. But a moment's thought will make it clear that, so long as our suspensions are unstandardised, our records of the strength of a serum are equally unreal, whether we use dilutions or units. There is no fundamental difference whatever between the two methods of expression, for the figures given by the one are merely the reciprocals of those given by the other. None the less, the first method has certain disadvantages from which the second is free.

(1) Expression in dilutions conceals the inner meaning of the system of measurement. If the words "standard" and "unit" had originally been employed it would always have been clear to all that the standard and unit in use were greatly in need of improvement.

(2) It is more bother to record fractions than simple figures. The mild irksomeness of writing fractions has, in fact, driven most serologists to record only the denominator of their dilution figures—e.g., to write "titre 1000" for titre

1/1000. Thus it is interesting to see that people have slipped into the way of recording their results actually, though not explicitly, in units (though not "standard" units).

For the reasons just given it is tolerably clear that an explicit recording in units is always preferable whatever system of measurement be adopted. A measurement which cannot be expressed in units is simply not a measurement and should be relegated to the sphere of mere qualitative observations. Every worker who expresses a result as a titre, without reserve or qualifications, assumes the existence of a standard and a unit. Otherwise, the figure he gives is absolutely void of meaning.

Methods Hitherto Employed.

We have come in our argument to this point.

(1) The common method of estimating "titre" of agglutinating sera makes use, as all methods of measuring must do, of a "standard" and of a unit. The standard is the 24-hours' living suspension of the specific organism, assumed erroneously to be of sufficiently constant agglutinability. The expression of "titre" in dilutions is simply an expression of the reciprocal of the strength of a serum in units measured by this standard.

Most workers have realised that there should be standard conditions of time, temperature, &c., for their reactions, and they at least do not omit to mention what conditions they apply to their tests. Some, however, while expressing their results in reciprocal units (i.e., dilutions), fail to realise that by omitting all mention of these fundamental experimental conditions they destroy whatever reality their measurement may have had for other workers. It is as though one man should ask of another, "How wide is the river?" and he should answer, "Fifty."

(2) The standard adopted in this method is a bad one.

Undoubtedly it has been better than none at all, for it has enabled a certain stage of knowledge to be reached. It is a bad standard because a highly variable one. Usually approximately true within certain wide limits, its fluctuations could on occasion be calamitous. Even if a single uniform technique had been in vogue the system was only capable of giving an answer comparable in precision with the schoolboy's answer: "It's as big as a lump of cheese."

The first, so far as I am aware, to realise the inherent weakness of the standard was Madsen, who devised a method whereby fluctuations of agglutinability in suspensions were discounted.

When measuring the power of an unknown serum he always compared it with a known serum, using the same suspension in testing the two. The strength of the unknown serum could then be expressed in terms of the known "standard" serum. By this method differences in the strength of two unknown sera could be determined with a fairly high degree of certainty.

It suffered, however, from the important weakness that all serums are unstable, and that therefore his standard was a constantly shifting one. This defect was remedied by Dreyer,² who worked out the technical process whereby bacteria can be made into suspensions of such stability as to be available as a trustworthy standard material on which to measure the agglutinating power of sera.³

Essentials of Dreyer's Process.

The main essentials of the process may briefly be stated as: (1) growth of the organism in simple fluid media such as broth; (2) sterilisation with formalin in the cold, by the addition of just enough formalin to kill and fix the bacilli (0.1 per cent.) and no more. These steps succeed in procuring a suspension of the following characters.

(a) The bacteria are dead and fixed, like museum specimens, and therefore do not autolyse. Autolysis in the early stages of the fixation process, which takes a few days, is largely inhibited by the low temperature.

(b) The organisms remain in the surroundings in which they grew up. This avoids damage such as is done in the violent exposure of agar cultures to the disintegrative influence of pure salt solutions.

(c) The suspensions contain no excess of antiseptic which might undergo change into acids or other bodies detrimental to the suspensions.

¹ Dreyer's expression "agglutinin unit" is objected to by some as a false expression which assumes the existence and measurability of a definite substance called agglutinin. But no such assumption is made by Dreyer, who employs the expression as a convenient abbreviation of "unit of agglutinating power." Perhaps it would be better to use the latter expression and avoid the word agglutinin, though it is a considerable convenience.

² Dreyer, G.: Hospitalstidende, No. 19, 1906; and Journ. of Path. and Bact., xiii., 331, 1909.

³ The scope and purpose of this article makes it unnecessary to mention the immensely important work of other pioneers in agglutination technique.

(d) There is either no loss of agglutinability at all (e.g., the typhoid group) or a transitory loss of no importance (*B. dysenteriae*).

(e) The characters of an emulsion are preserved for years without change.

(f) Successive suspensions of any strain can be tested against each other, and each can be given an "agglutinability-constant" which expresses its precise degree of agglutinability relative to one of the suspensions arbitrarily chosen as standard. This process, then, provides us with a method whereby true measurements of the power of any serum may be obtained; for we have a stable and trustworthy standard of reference, which confers on our measurements a reality which was unattainable by means of the bad standard hitherto in use.

Its Scope and Limitations.

Before discussing the scope and limitations of Dreyer's standard unitary method and in order to clear the ground it must be clearly stated that the principle of the method is of theoretically universal applicability wherever quantitative agglutination tests are to be made, whether they form a part of experimental or of routine clinical work. Let us first of all consider its application to a kind of research that is much practised at the present time.

Suppose we have obtained from a clinically similar group of sick persons a number of strains of bacilli whose main cultural characters are those of some already known organism. We propose to identify fully and classify the bacilli by means of cross-agglutination tests. So we make a number of agglutinating sera with stock strains of the known organism and with each of the bacilli we isolated. The question arises, How shall we make the suspensions to be used in the tests? The decision depends upon whether or no we take into account the fact that no two sub-cultures of a strain can be assumed to have the same degree of agglutinability.

It will be of interest to compare the results of neglect of the variability-factor with the effects of its recognition in an imaginary research. Suppose we are testing one of our new recently isolated strains against the known bacillus, cross-agglutinating both with sera made from each. We make to-day a living saline suspension of each bacillus. We standardise the bacterial content by some adequate method, in order to eliminate the effect of variations in the mass of bacilli acted on. We test them both with the serum of the known bacillus ("known serum") and find that the highest dilution in which known bacillus is agglutinated is 1/1000. The reading for the unknown bacillus with the same serum is 1/500.

The next step, which we carry out the next day, is to test the two strains with the serum made with the unknown bacillus (unknown serum). So we make two fresh living suspensions as before, put up the test, and obtain the following readings.

Unknown serum { Known bacillus 1/1000.
Unknown bacillus 1/2000.

What conclusions can we draw from these two tests? We can undoubtedly conclude that the two organisms belong to the same group, but what about their serological identity? We can draw no conclusion whatever.⁴ And the reason is that in the former experiment we may, for all we know, have been dealing with a "known bacillus" suspension of supernormal agglutinability and in the latter with a normal or subnormal suspension. "Unknown bacillus" may have given yesterday a roughly normal suspension, to-day one of high agglutinability. If this has been the case, our results are compatible with a complete serological identity of the two strains.

But it may equally well not have been the case. We can with equal reason suppose that yesterday's "known" suspension was of low sensitiveness and the "unknown" suspension supernormally sensitive, while to-day we have happened to meet with reversed conditions. In this case it is clear that the two experiments have made the strains appear much more similar than they really are.

These experiments, therefore, leave us absolutely in the dark as to the true relationship of the two strains, and all because we have failed to eliminate the variability-factor of suspensions.

It may be objected that in the instance given variations in agglutinability of 100 per cent. are represented, and that such variations do not occur, or at least are rare. But they undoubtedly do occur, and by no means uncommonly. And in any case if it be granted that they occur at all, it follows

⁴It has been suggested to me that my illustrative examples are unconvincing, because nobody pays any attention in practice to variations of less than several hundred's per cent. If this be true, it constitutes an admission of the scientific weakness of current methods.

that every test of the nature described is necessarily an object of suspicion. Again, it may be objected that any sensible person would test the two sera of our illustrative experiment on the same day, using only the one suspension of each strain for the purpose. Yes, but he may have scores of strains to test with dozens of sera, and he cannot possibly test them all on the same day. He will therefore have to make more than one suspension of some strains, since unformalised suspensions do not "keep."

I have attempted to make it clear that variations in sensitiveness of successive cultures of an organism have vitiated the quantitative of our agglutination tests, and have had the effect at the best of hiding otherwise ascertainable facts, or, if we are unaware of the weakness of our method, at the worst of leading us to definitely erroneous judgments.

Advantages of Dreyer's Method.

Now let us, in imagination, repeat the same experiment with Dreyer's method.

Dead formalised cultures of the two strains are made and diluted to the requisite density. It would be best, of course, to make enough of each to last through the whole series of experiments; but let us suppose for the sake of demonstration that we are compelled by circumstances to prepare new suspensions for each experiment. For the first day's test, then, we have suspension (1) of unknown bacillus, and suspension (1) of unknown strain.

With the known-strain serum we find that first known suspension gives its end-point at 1/1000, and first unknown suspension at 1/500. These two suspensions are our standards for the two strains, and the remainder of each is stored until our next experiment. Some days (weeks or months) later we test the unknown-strain serum on two new suspensions.

As a preliminary we test the second "known" suspension against the first known suspension (with the homologous serum) and find that it possesses only half the agglutinability of suspension No. 1—i.e., that it takes the double quantity of serum to agglutinate it to the end-point. By the same process unknown suspension No. 2 is standardised against unknown No. 1, and its agglutinability is found to be double that of No. 1. We can express the findings thus, placing the sensitiveness of the standard suspension in each case as unity.

Suspension.	Agglutinability-factor.	Suspension.	Agglutinability-factor.
Known No. 1	1.0	Unknown No. 1	1.0
Known No. 2	2.0	Unknown No. 2	0.5

We now carry out the test of the two No. 2 suspensions with the unknown serum, and we obtain these readings:—

Known susp. No. 2, 1/1000. Unknown susp. No. 2, 1/2000.

Before forming any opinion as to the meaning of the results we translate the figures into standard units thus:—

Reciprocal of dilution.	Agglutinability constant.	Standard units.	Reciprocal of dilution.	Agglutinability constant.	Standard units.
Known serum.			Unknown serum.		
Known culture. (1), 1000.	1.0	1000	Known culture. (2), 1000.	2.0	500
Unknown culture. (1), 500.	1.0	500	Unknown culture. (2), 2000.	0.5	4000

From these figures we conclude that each serum agglutinates its own strain more highly than the other strain, and therefore that our experiments have yielded *prima facie* evidence that the strains are serologically distinguishable. This information could not have been obtained with unstandardised suspensions, as we have seen.

The Value of Standardisation.

I need not elaborate the argument by showing what our conclusions would be if we found agglutinability factors other than those postulated. For whatever they may have been, our experiments would have yielded a definite piece of information which we could not have obtained with unstandardised suspensions. The reader will have noted that the argument is based on the belief that any two subcultures of an organism give a constant ratio of agglutinability when tested with any number of sera. This belief is not a mere assumption, but rests on much routine experience and on direct (unpublished) experiment. The only published observations that weigh in any way against its truth are in the Medical Research Committee's Report mentioned above. It may be well to take another instance of the value of standardisation in agglutination experiments.

An experimenter wishes to study the variability of individual strains of bacteria as regards morphological, biochemical, and serological properties, and to attempt a correlation, if possible, of the various changes. Of this research it only concerns us to deal with his agglutination tests and to show how, by standardisation of his materials, he can ascertain facts which he could discover by no other means. His method, we will suppose, is to grow a strain of bacilli on some special medium for six months and to test its behaviour at intervals. If he is unfamiliar with, or distrustful of, the principle of standardisation he will naturally carry out his tests with fresh cultures of the organism. He makes an agglutinating serum in sufficient quantity to last over the whole experiment, and with it he tests the suspensions made, let us say, one every week.

Plotting a curve from these observations he finds it to be very spiky and wobbly ("experimental error" he calls this) and to show a slight but constant decline.

What conclusion can we scientifically draw from such a curve? He can only say: either the culture has remained unchanged in sensitiveness, while the serum has degenerated slightly; or the agglutinability of the culture has increased somewhat, but the serum has lost enough to overbalance that change; or, both the culture and the serum have lost very slightly.

In fact he remains in ignorance of what has occurred.

On the contrary, if he avails himself of the principle of standardisation, he will make at the outset of the experiments a good quantity of killed, formalised culture, and will make a careful quantitative comparison of each new specimen with this standard suspension by means of a stock homologous serum. In this way he can work out a trustworthy curve of the rise or fall of agglutinability of the living culture. If his standard suspension runs out during the course of the research, he will have made a second one, and standardised it against the first. By means of the reduction factor the curve can be levelled at the point where he changed over to the second standard culture.

A Plea for Recognised Standard Type Cultures.

These two instances must suffice to illustrate the general applicability of the standard principle to quantitative agglutination work in any particular series of experiments, and we will pass on to the question of its wider application in the form of publicly recognised standard cultures for use in routine tests and as starting-points in research work.

So soon as properly conducted researches have succeeded in making a provisional serological analysis of a hitherto uncharted group of organisms, a central institute can be directed to manufacture on a large scale standardised suspensions of the various type-strains which represent the most salient constituents of the group. It should be made clear to all who make use of these type-standard cultures that the act of official manufacture does not imply any dogmatic sense of finality as to the constitution of the group, but is simply a step taken for the convenience of workers in that field whereby fixed points are provided for the starting of further research.

Incidentally, the standard cultures may at once be tested on a large scale for the purposes of clinical diagnosis of infections with the group; and it can be determined which of them it is necessary to employ in order to secure the maximum of certainty in routine investigation. The Standards Institute would then adopt the policy of supplying the necessary cultures (and corresponding sera) to clinical workers in this field, together with an explanatory pamphlet.

The actual standardisation of the cultures and the proper use of the reduction-factor by clinical workers would ensure the uniformity of records, and thus facilitate the accumulation of material which would have a far greater statistical value than similar records obtained by an unstandardised method.

The minor advantages of a central supply of material for routine diagnosis were made obvious during the late war. These are reliability and sterility of the cultures and the saving of time to individual workers.

Since the cultures are standardised they can always be employed in tracing the rise and fall of the agglutinin curve in infected or inoculated persons or animals with a precision exceeding by far that obtainable with unstandardised suspensions.

Returning to the more important question of experimental work, I must explain more clearly how standard cultures may act as fixed points for further research.

A worker of repute has, for instance, classified a group of bacteria into two main types, and his work is confirmed, in the main, by other independent observers. The Standards

Institute obtains his type bacilli, puts them through a thorough experimental investigation, and confirms the findings. So standard cultures are made with the type-strains and offered for circulation.

Another worker wishes to experiment upon the permanence of the stock types—i.e., to find out whether they do or do not alter their serological characters from time to time.

From what we have already seen, a proper standard technique is necessary if such a research is to obtain all the available evidence. This being so, it will be not only a convenience to the worker himself if he can obtain reliable standard cultures of the type-strains instead of having to start ab initio and make his own, but there will also be a definite gain to the scientific community in the fact that he will be using the same standard unit as everyone else for these type organisms, instead of erecting for himself, without any advantage to himself or anyone else, a new standard unit for each. For every strain used in his research other than the stock types he will have to make his own standard unit, until it be proved for certain that the strain is serologically identical with one of the stock types. If the work shows that the officially standardised strains do not adequately represent the whole group their number can, of course, be increased.

Now suppose that it has been conclusively shown that every strain of the group varies from time to time in serological characters, so that at one time a strain appears to be type A and at another time to be type B, and that its characters under no circumstances became fixed; then the principles of standardisation would no longer be applicable, for no single strain of the group would be a serological entity at all. Up to the present, however, no organism of any species has been shown to behave in this way, and therefore the principle holds good, in theory, for all bacteria.

We may ask, What is there in all this that can be objected to as limiting the individual freedom and confining the genius of experimental bacteriologists? The answer is—nothing. Those who believe in standardisation desire that a certain amount of pressure should be brought to bear (by persuasion) on workers to adopt the best technique available at any moment, and more particularly to employ a good and uniform standard of measurement in place of a bad and insulated one. They are convinced that Dreyer's system is by far the best technical method at the present moment, and is the only one which provides a really sound basis of measurement. We have seen that its application is confined at first to individual researches; then, as knowledge grows, provisional public standards may be adopted for the furtherance of research and for immediate clinical utility.

Finally, when the characters of an organism or of a group are established on a firm and unshakable scientific basis, we may settle down to an unqualified acceptance of universal standard cultures for the organism or types of the group, for use both in clinical work and in experiments of all kinds. Even this latter could never restrict the liberty of workers, who would always have perfect freedom to invent a better system and replace the old standards with better ones. It would, in fact, always be one of the first duties of a Standard Institute to work perpetually on the betterment of existing standards and the discovery of new ones.

EXPERIMENTS ON THE AGGLUTINATION OF *B. PARATYPHOSUS* A.

The advance of experimental method in bacteriology, as in all sciences, calls from time to time for a reconsideration of accepted doctrines; and in no question is this more frequently necessary than in that of the classification of bacteria. In the last few years there has been a strong tendency towards the subdivision of species, hitherto accepted as entities, into a variable number of types or fixed varieties. The pneumococcus, the meningococcus, Flexner's bacillus, the bacillus of influenza, and several pathogenic anaerobes have in turn been submitted to the analytic process. I am speaking of serological analysis, for this is a comparatively recent addition to the experimental outfit of a bacteriologist.

That in the great majority of cases these subdivisions reflect the truth to a greater or lesser degree I have no doubt; but it is often difficult to avoid the belief that the experimental technique employed has contributed an element of illusion to the findings. For instance,

¹ Or to supply standard suspensions to the manufacturers, and to check and control the circulation of the manufactured article.

the faith placed by many workers in the absorption method of Castellani does not seem fully warranted. Opinions of experts are divided as to its value, and my own experience has led me to support the view that it yields no true information unobtainable by simple agglutinations. When we find our agglutinations and our absorptions give discordant results, why should we assume that the latter have revealed to us a higher truth than the former? We are still very ignorant of the processes underlying our serological reactions, and, this being so, it seems the best plan to simplify the issue of our experiments by employing a straightforward method and, at the same time, sharpening it to the greatest possible degree of accuracy.

The Serological Identity of Strains of *Paratyphoid A*.

The experiments described in this paper prove, in my opinion, by simple agglutination tests the serological identity of all the strains of *B. paratyphosus A* employed. Were I, or another, to go over the same ground with absorption tests and discover diversity among the strains my deduction would be that this test, by its greater complexity, had led our judgment into error.

I do not know whether the serology of *B. paratyphosus A* has previously been closely investigated, but even if it had been it would be none the less desirable to work over the ground by means of Dreyer's technique, which is free from certain sources of error inherent in methods which include the use of unstandardised saline suspensions of bacilli. With Dreyer's method the same suspension may be examined and re-examined repeatedly over long periods, with the knowledge that its agglutinability is not changing. Every suspension thus provides a fixed point from which one may calculate variables—a scientific gain which cannot but be apparent to all.

Even with this technique we have certainly not yet mastered all the minor obstacles which stand in the way of consistently accurate measurements of the agglutinating power of sera. For instance, we have something to learn about the variability of agglutinating sera made with different cultures of a species—a phenomenon of which apparent instances are recorded by Topley, Platts, and Imrie,¹ and which undoubtedly deserves very careful investigation. It is my belief that all the apparent anomalies found by these workers in the case of *B. paratyphosus A* and possibly also of *B. paratyphosus B* are to be explained as technical variations, and not as evidence of serological variability. This is the teaching I have always had from Professor G. Dreyer, and every new investigation of my own has served to verify rather than to contradict it.

In the present paper I present tables of the comparative agglutinabilities of some strains of *B. paratyphosus A* when tested with a number of different sera, then I discuss some apparently anomalous results and demonstrate by experiment that they are due to the variable reaction-time of suspensions of poor quality.

The aim of the experiments was to establish *prima facie* evidence, with the limited material at hand, of the validity or invalidity of the view that *B. paratyphosus A* is a serologically uniform species.

Method:—In all essentials the technique employed was that recommended by Dreyer, under whom I have had extended opportunity of studying it. Thus formalised broth cultures have been employed throughout (0.1 per cent. of commercial formalin), and the suspensions were diluted with 0.1 per cent. formalised saline to a density similar to that of the suspension (standard culture para. A No. 27) which was used throughout as the standard of comparison. It happened that one suspension (para. A Charing X) was made, by error, distinctly thicker than the rest; and it is likely that this circumstance contributed something to the bad quality and irregular behaviour of this suspension. A single suspension of each strain was used throughout the comparative tests.

Some preliminary experiments were carried out by means of the short (Widal test) series of four tubes with a control. From the readings of these tests figures of relative agglutinabilities can only be calculated by means of Dreyer's reduction table.² Although this method is subject to a certain degree of error, since the table cannot be taken as fully applicable to paratyphoid cultures of variable quality, nevertheless these experiments have been included in the figures given in Table II. (two such tests with serum A 733

and one each with serum Charing X and B.W.); for the figures obtained were found in actuality to be little more variable than those gained by means of the long series of tubes which was used in the remainder of the experiments.

The most important advantage of the long series lies in its facilitation of direct comparisons of degrees of agglutination in any two series which are to be read against one another. Moreover, the fact that a number of readings can be taken reduces the error due to differences in the size of the individual tubes. Flocculation proceeds more rapidly in a relatively narrow tube than in a relatively wide one, and this influence may, in extreme cases, cause variations of 20 per cent. in a single reading.

In the water-bath the water level was kept constant, so as to cover about half the column of fluid in the tubes. This has been my practice since 1916, when it was adopted to accelerate the flocculation of dysentery cultures. Independent observations on the importance of this factor have been made and published by Topley and Platts.³

Readings were taken at two hours and again after 18 to 24 hours at room temperature. In the experiments on reaction-time, however, it will be seen that the tubes were compared after varying periods, up to 24 hours or more, in the water-bath. The usual readings taken were at least one coarse (standard) and one fine (trace) reading at two hours, and one fine reading at 24 hours. In some experiments only the finest obtainable readings were taken, since coarser readings, when cultures of bad quality are involved, provide much less accurate measurements of true agglutinability.

The sera were made by inoculating rabbits intravenously with one or more doses of formalised suspension of the bacillus. Serum B.W. was a commercial serum, possibly polyvalent; but unfortunately its history cannot be traced.

Section I.—Determination of the Relative Agglutinabilities of Some Strains of *B. paratyphosus A*.

Table I. is included with the object of illustrating the fact that different suspensions of the same strain of *B. paratyphosus A* tend to show differences of agglutinability as great as those possessed by suspensions of different strains. All the strains but one came from a military hospital in France, and were never, so far as I know, put through any process of selection which could explain their fairly obvious homogeneity. The suspensions were mostly of poor quality for agglutination, as is so frequently the case with unselected strains of paratyphoid bacilli.

Table II. gives the results of cross-agglutinating eight strains of *B. paratyphosus A* obtained from all quarters of the world with three para. A sera. The figures obtained with serum 733 are averaged from four tests—those with serum Charing X from two tests, and those with serum B.W. spring from one test only. With the exception of culture A Charing X the deviations of the different figures from the mean are not wide enough to lend support to a theory of "serological strains." On the contrary, they may be taken as a demonstration of the uniformity of this group of cultures and sera from the serological point of view.

Culture para. A Charing X needs special consideration, since the wide variation of the figures obtained with it is highly suggestive of a serological variation. This question was therefore examined more closely, and it was found that the suspension was an exceedingly slow agglutinator—i.e., much more than two hours' incubation was required to bring it to its end-point of flocculation. In another respect also it was a very bad suspension, for its flocculation was always very incomplete.

Table VII. presents a reaction-time experiment performed with this culture (called culture Ch.X), wherein its velocity of flocculation is compared with that of a standard culture of good quality. Two different serums were employed, one homologous with culture O, the other with culture Ch.X. In both cases culture Ch.X shows a relatively very low agglutinability in the early stages of the incubation, but when incubated for longer periods manifests an agglutinability actually exceeding that of the standard culture.

The different effect of the two serums employed will be discussed below. From this experiment it is easy to see how such aberrant and variable figures as those in Table II. can be obtained with such a culture. Thus, an apparent exception to the serological uniformity of the strains dealt with proved on closer examination to be an unreality, due to the peculiarities of the particular suspension and not to a true serological divergence of this strain from the others. In a recent paper E. C. Hort⁴ correlates vagaries in agglutin-

ability with the morphological characters of different suspensions. The few observations I have made on this point lend no support to his view, but it is one that calls for attention.

In Table III. is presented an additional series of experiments done with four of the same cultures as in Table II., but with the addition of two more sera. The figures represent the relative agglutinabilities of the cultures as found in a single test and calculating from two hours' readings only. With the exception of culture A 335 there is comparatively little variation in the relative agglutinabilities shown by the different cultures. 335 shows a much higher agglutinability with its own serum, and this might be taken as evidence of a true serological difference. It was therefore necessary to investigate the matter further by means of a reaction-time experiment. (See Table VI.) This culture was nearly as bad as culture A Charing X, and it proved to have a very slow flocculation-rate.

It has already been shown, in Table II., to be the second most variable suspension in the series. Its slow flocculability seems fully sufficient to explain how values so divergent as 175 and 88 can be obtained when different sera act upon the suspension and when the period of incubation terminates at two hours. The higher relative agglutinability manifested under the influence of homologous serum is discussed in detail in the next section.

Summary of Section I.

In cross-agglutination tests of eight strains of *B. paratyphosus* A, obtained from widely different sources, with three different sera, and of four of the strains with five sera, no evidence was obtained of true serological differences among the strains. In two cases the figures were distinctly irregular, and were at first thought suggestive of true differences; but an examination of the specific behaviour of the two suspensions concerned led to the explanation of these differences by the incomplete, and, more particularly, extremely slow agglutinability of the suspensions. Prima facie evidence of the serological uniformity of the species has thus been established by means of a technique which allows comparative measurements to be made with considerable precision. To place the matter on a complete scientific basis a larger material will have to be examined.

Section 2.—The Rate of Flocculation of Formalised Broth Cultures of Paratyphoid Bacilli.

No one who has employed in a macroscopic technique a large number of suspensions of bacilli, either in salt solution or in diluted meat broth, can have failed to notice the irregular quality of suspensions of different strains and of successive suspensions of the same strain. They may be divided roughly into good and bad suspensions, according as they show complete flocculation with sufficient doses of a suitable serum, and a relatively rapid approach to the end-point of the reaction, or, conversely, a poor and partial flocculation and a slow reaction-time. Typhoid bacilli usually make good cultures, and paratyphoid bacilli commonly bad ones.

By a process of selection and cultivation in fluid media *B. paratyphosus* A can usually be induced to grow in such a way as to produce sufficiently good cultures, but failures are apt to occur even when these means are employed. Broth suspensions of para. A in the absence of special cultivation are more frequently bad than good, and cultures of para. B are, in my experience, almost invariably bad. In the manufacture of standard agglutinable cultures of the last-named organism this difficulty has been to a considerable degree overcome by the employment of a special selected breed of bacillus which grows spontaneously in loose clumps, the elements of which, when separated by a process of formalising, cold storage, and mechanical shaking, are peculiarly susceptible to rapid and complete flocculation by agglutinating sera. The occasional occurrence of colonies of this type of organism in platings of an ordinary *B. paratyphosus* B was demonstrated to me by Professor Dreyer, and I have had considerable opportunities of observing its characteristics, which will be described on some more appropriate occasion.

No such method of controlling the quality of para. A suspensions has yet been discovered, and the production of good material here has depended upon a process of selection combined with an element of chance. In the routine work of the Oxford Standards Laboratory success has not been uniform, and a great quantity of para. A culture has had to be discarded from time to time on account of its inferior quality. Occasionally during the war inferior cultures had to be issued, because demands were insistent and poor

material was preferable to no material. Of such a nature were standard cultures para. A 23 and 32, which were among those employed by Topley, Platts, and Imrie in the research mentioned above. It is my belief that the discrepancies between their figures and the official ones in their Tables VII. and IX. particularly are an expression of the variability of the reaction and of the difficulty of observation of results obtained with second-rate material.

These facts, indeed, are a strong demonstration of the necessity of using good material for agglutination tests, and the best way of securing good material for all workers is by having it produced in properly equipped central institutes by specially trained persons who have the leisure to investigate the causes of inferiority in cultures and the means of improving them. It seems that fluid cultures of paratyphoid bacilli (and probably all bacteria) are composed of elements of variable agglutinability. When the conditions of growth favour the more highly agglutinable individuals a culture of good quality results, but in another set of conditions the elements of low sensitiveness outgrow their fellows, and the resulting culture is a bad one. All varieties, even down to apparently inagglutinable cultures, may occur. But the average bad culture seems to consist of a majority of bacilli which fail to flocculate within the time of observation and a minority which are readily flocculated. The latter, however, being scattered through the fluid, take a considerable time to come into contact with each other and so to form visible clumps. Convection currents in the fluid naturally facilitate the meetings of these elements, and so we find that the exposure of the upper part of the tubes to a lower temperature than the lower part has an even more evident accelerating effect on bad than on good cultures.

Table V. presents a simple case of a bad culture (para. A 34) with a slow reaction-time. At the end of three hours at 50–55° C. the good culture (A 27) appeared to be 4·17 times more sensitive than the bad one. Later reading of the tubes kept at the same temperature showed a progressive change in the ratio of agglutinability, until at 24 hours it was found to be only 1·22.*

TABLE I.

Twelve 24-hours' broth cultures of various strains of *B. paratyphosus* A roughly formalised and diluted to approximately the same opacity and agglutinated simultaneously by a serum made with strain 733. Short series of tubes. Date of experiment 19/3/1918.

Name of strain.	Date of stock culture from which broth culture was taken.	Actual readings (2 hrs.)		
		1/100	1/250	1/500
Para. A 335	15/6/16	t. —	? tr.	0
" 333	17/6/16	t. —	0	0
" Cairo 1	25/8/17	t. —	tr. +	0
" 627	17/6/16	t. —	0	0
" 674	29/6/16	t. —	0	0
" 666	27/12/15	t. —	0	0
" 360	17/6/16	t. —	0	0
" 733	29/1/17	t. —	? tr.	0
" 733	6/6/17	t. —	s.	0
" 733	22/2/18	t. —	tr. —	0
" 733	18/3/18	t. —	0	0
" 733	23/1/18	t. —	s. —	0

Symbols used.—t. = total; s. = standard (partial); tr. = trace of agglutination. The minus or plus sign appended signifies that the degree of agglutination was somewhat less or somewhat greater than the symbol states.

This experiment illustrates the view that different cultures of the same strain of this species show fluctuations of agglutinability as wide as those found in cultures of different strains.

TABLE II.

Cultures.	Sera.				Errors.			
	S. 733	S. Ch. X	S. B.W.	Mean.	S. 733	S. Ch. X	S. B.W.	Mean
Para. A.								
1	94	130	126	117	19·7	11·1	7·7	9·5
3	73	60	63	65	12·3	7·7	3·8	7·9
228	142	144	142	143	0·7	0·7	0·7	0·7
Cairo 1	162	183	150	165	1·9	10·9	9·1	7·3
335	200	140	175	172	16·3	18·6	1·7	12·2
Charing X	800	136	346	(422)	(90·0)	64·0	18·1	57·7
2	87	119	106	104	16·3	14·4	1·9	10·9
733	100	100	100	100	—	—	—	—
				Average 11·2		10·6	4·1	8·1

The figures given are the relative serum quantities required to agglutinate the various cultures to the same degree (2 hours' and 24 hours' readings averaged). They are therefore reciprocal to the relative agglutinabilities of the cultures.

* It was observed long ago by Dreyer and Jex-Blake (1905)² and Dreyer and Douglas (1910)⁶ that an improvement in the accuracy of comparative readings was obtained by a second reading of their tubes after some 18–24 hours at room temperature. They worked, naturally, with suspensions of good quality, which do not need a prolonged incubation period to attain maximal flocculation.

TABLE III.
Five sera with four cultures (single tests).

Cultures.	Sera.				
	Para. A 2.	Para. A (B.W.)	Para. A 335.	Para. A Charing X.	Para. A 733.
A 733 ...	100	100	100	100	100
A 228 ...	135	130	105	145	133
A C 1 ...	147	139	141	167	141
A 335 ...	—	175	88	141	135

The figures represent the reciprocals of the relative agglutinabilities of the four cultures with each serum. A 733 (a stock standard suspension) taken as unity in every case. Two hours' readings only.

TABLE IV.

Time in water-bath.	Serum A 41.		Serum A 29.	
	Cult. A 14.	Cult. A 29.	Cult. A 14.	Cult. A 29.
1 hr. ...	100	133	100	91
3 hrs. 40 m. ...	100	79	100	69
6 " ...	100	76	100	66
23 " ...	100	67	100	54

The figures represent the relative quantities of serum required to give a trace of agglutination. The table shows that Cult. A 29 has a slow flocculation-rate with both sera, compared with Cult. A 14. There is an indication of a slight acceleration by its own serum in the first hour.

TABLE V.

To show the slow rate of flocculation of a bad para. A culture.

Time in water-bath.	Cultures.	
	Para. A 27.	Para. A 34.
3 hours ...	100	417
5 1/2 " ...	100	180
10 " ...	100	135
24 " ...	100	122

Para. 27 is a good culture; para. A 34 a bad one. Figures represent the relative quantities of serum required to give a trace of agglutination.

TABLE VI.

Serum A.				Serum B.			
Incubation time.	Quantities of serum.		Ratio.	Incubation time.	Quantities of serum.		Ratio.
	Cult. A.	Cult. B.			Cult. A.	Cult. B.	
$\frac{1}{2}$ hr.	0.600	>1.00	>1.67	$\frac{1}{2}$ hr.	0.640	0.800	1.25
$1\frac{1}{2}$ hrs.	0.200	0.275	1.38	$1\frac{1}{2}$ hrs.	0.300	0.263	0.88
$\frac{6}{2}$ "	0.150	0.145	0.97	$\frac{6}{2}$ "	0.245	0.187	0.76
24 "	0.140	0.100	0.71	24 "	0.200	0.140	0.70

Serum A and culture A = Oxford Standard para. A culture No. 27 and homologous serum (strain para. A 733). Serum B and culture B = serum and formalised suspension made with strain para. A 335. The reading given in every case is that of the finest trace of agglutination observable.

TABLE VII.

Serum O.				Serum Ch. X.			
Incubation time.	Quantities of serum.		Ratio.	Incubation time.	Quantities of serum.		Ratio.
	Cult. O.	Cult. Ch. X.			Cult. O.	Cult. Ch. X.	
2 hrs.	0.40	>1.00	>2.50	2 hrs.	0.30	0.35	1.17
4½ „	0.30	0.45	1.50	5 „	0.29	0.20	0.69
				7 „	0.25	0.16	0.64
22 „	0.25	0.15	0.60	22 „	0.22	0.13	0.59

Serum O and culture O = Oxford Standard para. A culture No. 27 and homologous serum (strain para. A 733). Serum Ch. X and culture Ch. X = serum and formalised suspension made with strain para. A Ch. X. In every case the reading is that of the finest trace of agglutination observable.

It must be noted that trace-readings only are used in the comparison. Coarser readings would give different ratios at all stages, and by their means it would not be possible to judge the true agglutinability of the bad culture, for it is only the agglutinability of its most sensitive bacilli that can be properly estimated. This being so, it is easy to see how different observers may arrive at different ratios of agglutinability when working with inferior suspensions.

The culture para. A 34, though intended for a standard agglutinable culture, was withheld from issue by the Standards Laboratory on account of its bad quality.

Variations in Behaviour of Different Specific Serums.

Before entering further into the question of reaction-time some observations must be made concerning certain variations that occur in the behaviour of any pair of para. A suspensions when acted on by a number of different specific sera. Without assuming to lay down any rules of universal validity, I will state shortly the opinions to which experience has led me.

(1) A pair of good suspensions will give an almost, but not quite, identical ratio of agglutinability with all specimens of specific serum.

(2) The small differences of ratio are real and permanent, reproducing themselves constantly when the same pair of cultures are re-tested with the same serums after a year or more.

(3) The worse the quality of the culture the more pronounced do these differences become.

(4) A bad culture shows during the early hours of incubation a relatively greater sensitiveness when tested with its homologous serum than with heterologous sera. Possibly all cultures show this to some degree. Heterologous sera vary in their effects on a bad culture. Some agglutinate it more rapidly than others.

The special effect of homologous serum can be explained as an increase in the velocity of flocculation, which may perhaps mean that a larger number of elements is capable of being flocculated readily by this serum than by other sera. If a special term be needed as a label for it I suggest "super-specific acceleration."

This phenomenon must be taken into account in the interpretation of cross-agglutination and absorption tests on different strains of a species. So far as my experience with the "enteric group" goes, it is only one of several dimly understood phenomena, each of which may in certain circumstances lead our judgment astray. "Super-specific acceleration" seems to be important only when poor suspensions are in use. There is, indeed, a body of opinion that accuses agglutinin reactions of tending sometimes to give rise to unreal subdivisions of bacterial entities, and we must assuredly adopt a rigidly sceptical attitude in interpreting our experimental results. Tables VI. and VII. provide good examples, similar to that in Table V., of agglutination tests which could not fail to be misinterpreted if a short-period reading were the only one taken. In each of these experiments a bad culture was measured against a good one, using first the serum homologous to the one culture and then the serum homologous to the other. In both alike the ultimate ratio of agglutinability after long incubation is identical. In both alike the bad culture has the slower flocculation velocity, and in both its velocity is very much higher with homologous than with heterologous serum. The bad culture C.X in Table VII. is the culture para. A Charing X of Table II. So imperfect was the flocculation of this suspension that even the strongest serum dilutions caused only partial agglutination. Attention was called to it as the only culture which showed such serious fluctuations with the different sera as to throw doubt upon its identity with the rest of the strains.

We are now in a position to form a truer judgment. Table VII. shows clearly how variable may be the ratios found unless prolonged incubation is carried out; but that, when it is carried out, the two ultimate ratios are the same.

It is easy to imagine that, with a suspension even more refractory than this one, one might fail altogether to reach the real end-point when using any but the strictly homologous serum. A precisely similar experiment is given in Table VI. Here the bad culture is para. A 335, which was seen in Table II. to show a degree of variability greater than any save para. A Charing X.

In the present table it manifests a variation similar in direction but inferior in magnitude to that of para. A Ch.X in the last table. Even when a pair of suspensions of the same strain are tested in this way first with a serum made with the one suspension, and then with a serum made with the other, there seems to be a tendency to this super-specifically elective action, but I have not made any sufficient experimental examination of this point.

Whether or no it can all be explained by reaction-time phenomena, there is no doubt that the ratio of agglutinability of any pair of suspensions may show definite and constant differences of a minor degree when the cultures are agglutinated by different sera.

The available evidence does not point to strain specificity as the true explanation of these minor differences, but rather to the interaction of other chemical or physical properties of the sera and the suspension, properties which must always

vary to a certain degree. The matter is, however, of sufficient importance to warrant a special investigation.

My thanks are due to Professor Dreyer for various suggestions, and to Miss J. Jorgensen for help in some of the experiments.

Summary.

1. Evidence is brought forward of the serological uniformity of a number of strains of *B. paratyphosus A* of widely different origins.

2. This constitutes prima facie evidence of the serological uniformity of the species.

3. Certain irregularities in the behaviour of some of the cultures are shown to be due to the variable rate of flocculation of inferior suspensions.

4. The greater sensitiveness of certain cultures to homologous strain sera is shown to be at least partly a reaction-time phenomenon, for which the term "super-specific acceleration" is suggested.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF

CESSATION OF RESPIRATION

FIFTEEN HOURS BEFORE DEATH.

By H. WALLACE JONES, M.Sc., M.D. LIVERP.,

HONORARY ASSISTANT PHYSICIAN, LIVERPOOL ROYAL INFIRMARY.

THE chief interest of the following case of cerebral hæmorrhage lies in the length of time during which the heart went on beating after spontaneous respiration had ceased and in the opportunity afforded of obtaining an electrocardiograph of the heart.

A married woman, aged 50, was brought to the Royal Infirmary unconscious and cyanosed with the history that she had suddenly become dizzy and fallen to the ground.

On admission she was markedly cyanosed and respiration had ceased. Her heart, however, was beating regularly and with considerable force at the rate of 120 per minute. Corneal reflexes were absent and no knee-jerks could be elicited. The pupils were equal and widely dilated.

Electrocardiogram taken in a case of cerebral hæmorrhage 12 hours after spontaneous respiration ceased. The vertical lines denote fifths of a second.

Artificial respiration was commenced at once and her colour rapidly became normal, the pulse-rate falling from 120 to 72 per minute; this was continued for two hours, during which time she made no respiratory effort.

It was then decided to use intratracheal insufflation of air, using Mr. E. E. Kelly's apparatus, which kept the patient's colour normal, the heart continuing to beat strongly as before. Lumbar puncture revealed normal cerebro-spinal fluid under slightly increased tension; the optic discs were normal, and the urine contained a slight trace of albumin but no casts. A surgical colleague was consulted with a view to performing a decompression, but as there

were no localising signs it was not thought to be justifiable. The insufflation was continued until the heart ceased to beat, 15 hours after admission.

The accompanying electrocardiograph was taken 12 hours after spontaneous respiration had ceased, and shows normal rhythm with some lengthening of the ventricular complex, which occasionally exceeds half a second in duration. Post-mortem examination showed a recent hæmorrhage in the right cerebral hemisphere destroying the internal capsule; both the lateral ventricles were filled with blood, and there was some flattening of the convolutions. The medulla and pons were normal; signs of general arterio-sclerosis and chronic interstitial nephritis were present.

NOTE ON A CASE OF

PRIMARY DIFFUSE ALVEOLAR CARCINOMA OF THE LUNG.

By A. KNYVETT GORDON, M.B. CANTAB.

A SPECIMEN, consisting of a portion of the upper lobe of the right lung, was sent to me for investigation by Dr. C. L. Lander, of Devonport, to whom I am indebted for the clinical notes of the case.

The patient, a woman aged 56, was well until four months before her death. The illness began with cough and dyspnoea, with very little expectoration and no hæmoptysis; she grew steadily worse, and took to her bed two months later. During the last month of her illness she suffered from severe attacks of dyspnoea with pallor, sweating, and rapid pulse. The physical signs were those of consolidation of the right lung.

Post-mortem the whole of the right lung except the inferior portion of the lower lobe was infiltrated with a homogeneous mass of growth, the pleura being adherent and thickened throughout. There was no sign of disease in any other organ, nor were there any obvious metastases; the bones, however, except the clavicles, were not examined.

Macroscopically, the specimen exactly resembled a portion of lung in the grey hepatisation stage of lobar pneumonia. It was homogeneous throughout, and there were no signs of cavitation or breaking down of tissue.

On microscopic examination the alveolar structure of the lung was seen to be well preserved, but each alveolus was filled with a papillomatous collection of columnar epithelial cells arranged on a delicate fibrous support of a dendritic structure, bearing, in fact, a striking resemblance to a miniature villous papilloma of the bladder. Beyond slight post-mortem changes there was no gross or localised necrosis. The bronchi were unaffected, and there was no evidence of concomitant tuberculosis. The pleura was thickened by chronic inflammatory change, and adherent.

The interest of the specimen lies in its rarity. Primary carcinomata of the lung are said to form about 1 per cent. of all carcinomata, and of these the great majority are of the squamous- or spheroidal-celled variety, arising either from the bronchial mucosa or glands. The alveolar carcinomata are again divided into the nodular and diffuse varieties, of which the nodular is the more common. The type represented by this specimen is therefore almost a pathological curiosity. In view, however, of the clinical and pathological similarity between this type of alveolar carcinoma and lobar or lobular pneumonia it is possible that the disease may not be so uncommon as appears.

Bedford-square, W.C.

A CASE OF

CONGENITAL SUPRAPUBIC HERNIA.

By F. M. NEILD, M.B., B.S. LOND.

WHILE examining coolies for the Chinese Labour Corps at Tsingtau in the spring of 1917 I came across a number of deformities and abnormalities. Among them was a case of suprapubic hernia of a type I have not seen described, though two cases of suprapubic hernia due to divarication of the recti have been published.

As the coolie presented himself for examination a rounded swelling about the size of a grape-fruit could be seen above and overhanging the pubes. On examination this proved to be a hernia with very thin coverings. The whole could easily be reduced and inverted within the abdominal cavity. The opening easily admitted the whole hand, and the entire pelvis could be explored. Above, the ring was arched and on each side attached below to the symphysis pubis. The edges felt sharp and were quite unyielding. The lower and narrower boundary was formed by the os pubis. The penis, scrotum, and inguinal canals were normal.

and the coolie was otherwise well developed. He stated that he had had the hernia all his life, that it did not tend to get any bigger, and did not interfere with his work. There were no urinary symptoms.

For lack of time I was not able to make a more detailed examination. The possibility struck me that it was due to absence of the lower ends of the recti and pyramidales muscles.

Shanghai.

A CASE OF MIKULICZ'S DISEASE.

By S. G. ASKEY, M.A., M.D., B.CH. CANTAB.

THE patient whose photograph is reproduced was 28 years of age, and came under my care in India with chronic amoebic dysentery. The parotid glands were greatly enlarged, of uniformly tough consistency, and not tender. The lacrymal glands were about twice their normal size. There was also some enlargement of the submaxillary and sublingual glands. The man stated that he had noticed his face gradually increasing in width for about three years. The thyroid was not enlarged, the spleen was not palpable, and the lymphatic glands of the axillæ and groins were not increased in size.

The literature of the disease is meagre and chiefly continental. Mikulicz observed the condition in 1888 and first described it in 1892. The aetiology is unknown,

Mikulicz's disease, showing glandular enlargement.

and the disease has been variously ascribed to (1) a general infection; (2) a local infection; (3) a primary neoplasmosis. Histologically the enlarged glands show some of the appearances of sarcoma, but though slowly progressive the enlargement is in no sense malignant. I have seen one case of 15 years' duration. Pressure from the enlarged lacrymal glands sometimes causes impairment of vision, and the eyeball may be displaced downwards and inwards. The glandular enlargement is said to subside during an acute intercurrent illness, or after removal of the main portion of the lacrymal glands. A number of drugs have been recommended for the treatment of the disease—arsenic, iodides, sodium cacodylate, pilocarpin, Coley's fluid, thyroid extract, and X rays have been tried, but without much effect. It is interesting to note that most of the cases described have occurred in coloured persons.

Highgate.

Reviews and Notices of Books.

RHEUMATISM AND ARTHRITIS.

By RALPH STOCKMAN, M.D., Professor of Materia Medica and Therapeutics in the University of Glasgow, and Physician to the Western Infirmary, Glasgow. Edinburgh: W. Green and Sons, Ltd. 1920. Pp. 132. 15s.

So many gaps exist in our knowledge of the so-called "rheumatic diseases" of joints that insuperable obstacles bar the way to anything approaching finality in the description and classification of these disorders. The exact clinical differentiation of several of the members of the group is still scarcely possible, and the inherent difficulties of the whole subject are added to by the confusion among authors as to nomenclature and morbid anatomy of these diseases. The present writer has largely confined himself to recording the results of his own clinical and pathological observations and theorising has been sparingly embarked upon. Historical notes are appended to the description of the various disorders and these go far to clear up the confusion of nomenclature to which we have already referred. Indeed, we think the author has rendered a signal service to the serious student by their inclusion. The term *fibrositis* is used by the author as synonymous with chronic rheumatism—that is, chronic inflammation of the white fibrous tissue of the body. Chronic inflammation of the areolar tissue of the panniculus adiposus is referred to as *panniculitis*. The morbid anatomy and causation of this condition do not differ in essentials from what is found in *fibrositis*, with which it may coexist. A short chapter is devoted to Dupuytren's contraction of the palmar aponeurosis, and "claw-foot" is regarded as an analogous state. A lengthy chapter is set apart for the consideration of chronic non-suppurative arthritis, under which term the author includes rheumatoid arthritis and several ill-defined conditions which at present can only be differentiated from one another to a very limited extent, and which are collectively referred to as chronic infectious arthritis. This is followed by chapters dealing with purpura rheumatica, gonorrhoeal rheumatism, arthritis of known causation—e.g., pneumococcal arthritis—and osteo-arthritis. Heberden's nodes have an interesting chapter devoted to their consideration. They are described as the result of a periostitis and osteitis rather than of osteo-arthritis. It is noteworthy that while all writers subsequent to Heberden describe the condition as a mild form of osteo-arthritis, yet Dr. Stockman in examining specimens has never met with the changes characteristic of true osteo-arthritis. The book closes with a consideration of coxa vara, hypertrophic osteo-arthropathy, and of nervous arthropathy. Little new light is thrown on the treatment of the conditions so lucidly described, and we are of the opinion that the chief merit of the book lies in helping to remove the state of mental confusion and incertitude which besets the student entering upon the investigation of "chronic rheumatic disease." The book is printed in clear type and is well illustrated by numerous photographs.

OPERATIVE SURGERY.

A companion volume to a "Manual of Surgery," Vols. I. and II. Third edition. By ALEXIS THOMSON, F.R.C.S. Edin., and ALEXANDER MILES, F.R.C.S. Edin. London: Henry Frowde and Hodder and Stoughton. 1920. Pp. 619. 16s. net.

THIS text-book of operative surgery, of which a new edition has been published, is well known and has long been valued. The text has been largely rewritten and rearranged, and matter has been added on some subjects which have undergone recent developments, such as artificial limbs and blood transfusion. A brief account of the main points in surgical anatomy has also been added. Although the number of the pages

has not been increased, a considerably larger amount of text has been printed on each page. Nevertheless, it is not possible in 600 pages to give a detailed description of most of the operations. Important operations are, indeed, barely mentioned, and in many cases the beginner using this book as his sole guide could hardly carry out with success the operations described.

The book is evidently intended for students who are acquiring an elementary general knowledge of surgical procedure rather than for those who are themselves engaged in the practice of operative surgery. With this fact in view we are less inclined to criticise its plan than we should otherwise be. Nevertheless, even though the student may acquire from the book a standard of knowledge adequate for the ordinary examinations in surgery, we regard it as unfortunate that it has not been brought thoroughly abreast of advances in surgical procedure. To take an instance. In the remarks on the technique of nerve suture, in which nerve-grafts and nerve-bridging operations are apparently considered quite satisfactory, a wrapping round the site of the suture seems to be regarded as essential, and no mention is made of the importance of preserving a small interval between the ends inside the sheath. In these points the authors run counter to recent teaching. Again, among the brief remarks on bone-grafting, no reference is made to Albee's "sliding graft," which is rapidly coming to the fore as the operation of choice in many cases, instead of plating or wiring. In the description of skin-grafting the free graft of the whole skin thickness, as distinguished from the pedicled graft, and various essential details of technique are not mentioned. After reading the authors' account of the time-honoured operations for placing an imperfectly descended testicle in the scrotum any student might suppose that they were found satisfactory in practice, whereas in fact they almost invariably fail. The only operation which does give some measure of success—namely, passing the testicle through the scrotal septum—is not mentioned. Syme's amputation of the foot is still described in the classical manner in spite of the fact that evidence accumulated during the last six years shows that a much higher section through the tibia and fibula gives better after-results.

Such instances might be multiplied. It is shortcomings of this kind, far too familiar in text-books of repute, that make the student distrustful, for he is taught in this way opinions and procedures which have long been modified or discarded in practice.

QUATRE LEÇONS SUR LES SÉCRÉTIONS INTERNES.

Par E. GLEY, Professeur au Collège de France; Membre de l'Académie de Médecine. Paris: J. B. Baillière et Fils. 1920. Pp. 160. Fr. 6.

THESE four lectures were originally delivered in Barcelona before the Société de Biologie in December, 1917. In compiling the present brochure certain additions to our knowledge of secretion of more recent date than the lectures, as well as a bibliography, have been added. The lectures do not claim to give an exposition or even a summary of the chief facts relating to the endocrine organs; they rather concern themselves with the method to be followed in researches on these organs and with the laws governing their mode of action—that is to say, the subject is approached from the physiological rather than from the medical point of view. The first lecture presents a critical exposition of the theory of internal secretion. The second examines the question as to what the essential function is which must be fulfilled before a gland can be regarded rightly as an endocrine organ. The third criticises the methods which too often have been employed in the past, and indicates the rational procedures which alone should be used in the study of internal secretion. The fourth lecture summarises the results which have been obtained up to the present time, and discusses their biological significance. The conclusion reached is that, despite mistakes of research in the past, the new ideas springing from the facts already obtained constitute a veritable revolution in biological knowledge.

A TEXT-BOOK OF PATHOLOGY.

Delafield and Prudden's Text-Book of Pathology. Revised by FRANCIS CARTER WOOD, M.D. Eleventh edition. London: John Bale, Sons, and Danielsson, Ltd. 1920. With 15 plates and 809 illustrations in the text. Pp. 1354. £3 3s.

It is becoming increasingly difficult to present the facts and theories of general and special pathology in a single volume; indeed, the task can only be accomplished by a process of rigorous pruning, and the attempt to include methods of technique is calculated to jeopardise its success.

In the eleventh edition of this well-known text-book the original plan has been adhered to, and the section dealing with the methods of making post-mortem examinations and with the preparation and examination of pathological tissues has been retained, though the hundred or more pages thus occupied might have been liberated with advantage for use in other sections. This adherence to tradition is, we think, regrettable, and the numerous references in the text to "the scope of this book" seem to show that the editor is conscious of the limitations which he has imposed upon himself. Certain important processes undoubtedly receive less attention than they merit. The description of œdema, for example, is very brief, and it is surely within the scope of any text-book of pathology to discuss the formation of anæmic and hæmorrhagic infarcts. On the whole, however, the necessary compression has been carried out wisely and well, and the text has been supplemented by copious references to the literature.

For this edition the text has been carefully revised and several of the chapters have been practically rewritten. Many excellent illustrations have been added, and we are confident that the work will continue to enjoy its justifiable popularity.

AMERICAN POCKET MEDICAL DICTIONARY.

Eleventh edition. Edited by W. A. NEWMAN DORLAND, A.M., M.D. London and Philadelphia: W. B. Saunders Company. 1919. Pp. 771. 7s. 6d.

THE last edition of this admirable desk companion contains several hundred new terms and bears evidence of careful revision. The preface states that the total sales to date of the pocket dictionary, since its first appearance in 1898, have amounted to over 185,000 copies. Suggestions and lists of new words sent by readers have been freely used in revision. Besides the strictly alphabetical arrangement, the dictionary contains 75 tables in which correlated facts are grouped. The only questionable feature is the table of doses (both for man and beast) in the metric system, given to three or more places of decimals, and well calculated to put the aspirant off the metric system for life—e.g., the dose of osmic acid is given as 0.00108 g. This is doubtless the correct mathematical equivalent of $\frac{1}{900}$ gr., but in practice the last two figures have no significance whatever. We appeal to the editor to use his vast circulation to popularise a rational use of the metric system.

THE DOCTOR'S MANUAL.

Or Practitioner's Vade-Mecum. With which is incorporated "How to Cut the Drug Bill." By A. HERBERT HART, M.S. London: John Bale, Sons, and Danielsson, Ltd. 1920. Pp. 256. 10s. 6d.

THIS is the fourth, or as the author puts it post-bellum, edition of a volume which has proved of value to the medical practitioner in its earlier forms. Dr. Hart is not one of those moderns who has no use for galenicals; he is a believer in the value of simple old-fashioned mixtures, and he tabulates with commendable detail a hundred or so of prescriptions which he has himself found useful in practice, grouping them under code letters for ease of reference and remembrance. This list forms the bulk of the first or older part of the book. The second part contains short practical chapters on anæsthetics, antipyretics, antiseptics, spas and mineral waters, invalid foods, and biological therapy. There is no attempt at scientific treatment, but the

practitioner will find useful practical details of where to obtain and how to use. The third part is an alphabetical synopsis of treatment which the author must have intended to be suggestive rather than complete. Mr. Frank Kidd, whose portrait is placed by the author on the title-page, contributes a special article on Venereal Disease, terse and to the point. The appendix contains a curious but quite serviceable assortment of tables for the practitioner's reference.

THE EXTRA PHARMACOPEIA.

Seventeenth edition, in two volumes. Vol. I. Revised by W. HARRISON MARTINDALE, Ph.D., Ph.Ch., F.C.S.; and W. WYNN WESTCOTT, M.B. Lond., D.P.H. London: H. K. Lewis and Co., Ltd. 1920. Pp. 1115 + xl. 27s.

A NEW edition of Martindale and Westcott's well-known and widely appreciated Extra Pharmacopeia is welcome. It is five years since the last edition (sixteenth) was published, many innovations have occurred since, and these are here comprehensively and faithfully dealt with. The work is a storehouse of accurate information and reference of value to medical practitioner and pharmacist alike. The former will note paragraphs dealing with the organic arsenic and antimony compounds, new coal-tar derivatives such as acriflavine and proflavine, the colloidal metals and non-metals, emetine, thorium compounds, and the vitamins. The latter will find an instructive and practical account of the manufacture of organic chemicals previously produced abroad. The successful preparation of these chemicals should, the authors hold, become more a matter of common knowledge. Many substances of admitted therapeutic value are the subjects of expired British patents, while their exact methods of production and their formulæ are uncertain. The Extra Pharmacopeia contains helpful information on these points, which should enable the qualified reader to obtain a satisfactory product by equally satisfactory procedure. The list of drugs coming within this category dealt with in the book seems exhaustive. There are chapters on vaccines; the authors set out the evidence in favour of the detoxicated vaccines. Throughout the whole work there is conspicuous evidence not only of thoroughness in actual compilation, but of personal investigation into many questions of importance in modern therapeutics. The Extra Pharmacopeia is not a text-book of pharmacology; it is not a critical digest of clinical experience. It does not set out to be either of these things; but within its limits, and with its records of pharmacological experiences, it is a book which the sister professions of medicine, pharmacy, and chemistry will consult with reward and advantage. Vol. II., to be issued later, deals with experimental work connected with the assay of chemicals and drugs, and contains sections on the composition of proprietary medicines, mineral waters, iontophoresis, radiology, with the addition of bacteriological and clinical notes. The Extra Pharmacopeia is one of the few books which medical practitioner, analyst, and pharmacist cannot afford to be without.

A SCIENTIFIC EXPLANATION OF CHRISTIAN SCIENCE.

By MICHAEL B. SHIPSEY, M.B., B.Ch. Birm. Birmingham: Cornish Brothers, Ltd. 1920. Pp. 23. 9d. net.

EVERY medical man knows that given two patients suffering from, say, pneumonia, the one who makes up his mind that he is going to recover will, *ceteris paribus*, be more likely to do so than the other who makes up his mind that he is going to die. In a way this is the principle upon which Christian Science goes, and thus far its doctrine may be sound. Dr. Shipsey has endeavoured to put the facts upon a scientific basis. Shortly, his thesis is as follows. Intense concentration of the mind upon anything is accompanied by a holding of the breath. Prayer is an intense concentration of the mind and equally a holding of the breath. In the case of a wounded or diseased part, the blood with its gases is forced by the guidance of the brain into the affected

part, which thus gains an extra blood-supply together with an increased supply of nervous stimuli. There is nothing impossible here, but when Dr. Shipsey comes to physiological and psychical matters he seems to us to flounder dismally. For instance, he says "the mind is really the animal electricity residing in the entire body, and when you concentrate the 'mind' on any particular part of the body it means that an excessive amount of animal electricity is sent to that part. When you look at an object in the distance a current of animal electricity (however feeble) passes to that object from the mind, setting up the process of vision in the brain." Again, "it has been well said that it is almost as hard to get a belief out of the human mind as it is to get the green colour out of a green leaf." Now nothing is more easy than "to get the green colour out of a green leaf," as any cook who has ever coloured food with spinach could tell Dr. Shipsey.

JOURNALS.

Quarterly Journal of Experimental Physiology. Editors: E. SHARPEY SCHAFFER, W. D. HALLIBURTON, C. S. SHERRINGTON, E. H. STARLING, A. D. WALLER. London: Charles Griffin and Co., Ltd. 1920. Vol. XII., No. 4. Pp. 303-401. 10s.—The Histology of Tadpoles Fed with Thyroid, by R. K. S. LIM. Previous observers have determined that the feeding of larval amphibians on thyroid and other endocrine glands determines a precocious differentiation of the body, with suppressed further growth. Tadpoles of *Rana temporaria* were fed at various periods after hatching, the majority with water-extracts of both fresh and desiccated (sheep) materials and with some pond weed. Microscopic studies were made on several series of tadpoles at different ages, and it was found that the nearer the animal is to metamorphosis the more intense is the effect of the thyroid; moreover, the effect appears to vary directly with the dose. Microscopic study shows that thyroid "accelerates the ageing," the number of mitoses are increased and developed, and consequently metamorphosis is induced and hastened. All organs appear more "adult" in character. The alimentary canal is first to be affected, a large thin-walled larval type of intestine being replaced by small, thick-walled type. Masses of pigment accumulate in the mucosa and may break through the epithelium. Thyroid-induced metamorphosis results in rapid absorption of the tail, the caudal muscles being disintegrated partly by phagocytes and partly by autolysis. The phagocytes loaded with muscle debris simulate eosinophil leucocytes, wander into the circulation and eventually are extruded through the intestinal mucosa. The number of blood corpuscles undergoing mitosis is increased. In general, normal processes are hastened and exaggerated by excess of thyroid hormones.—Observations on the Glycogen Content of Certain Invertebrates and Fishes, by L. G. KILBORN and J. J. R. MACLEOD. Using Pflüger's method for determining the amount of glycogen, it was found that the hepatopancreas of representatives of asteroidea contained 0.23 to 1.52, lamellibranchs 0.31 to 1.56, crustacea 0.05 to 1.39, elasmobranchs none to 0.21, teleosts none to 6.5, the amounts varying partly with feeding and partly with the season. As to muscles, lamellibranchs contained 0.07 to 2.67 (adductors), crustacea a trace to 0.36, elasmobranchs none to 0.02, teleosts none to 0.29. The glycogen content of the heart was several times greater than that of other muscles, and sometimes greater than that of the liver—for example, in the lobster. There may be 0.85 to 1.42 per cent. in the heart as against a maximum of 0.36 per cent. in the muscles.—Observations on the Reducing Substance in the Circulating Fluids of Certain Invertebrates and Fishes, by R. S. LANG and J. J. R. MACLEOD. The body fluid of echinoderms and molluscs contains little or no reducing substance. In some crustacea there is only 0.04 to 0.08, and in certain others only minute traces or none. In the dog-fish none or only a trace was found, while in chimæra and carp the amount was similar to that of mammalian blood (0.071 to 0.145).—Researches on the Perfused Heart: its Mode of Working, by W. BURRIDGE. The experiments were carried out on the hearts of *Rana temporaria* by methods and means already described by the author. The problem hangs round the salts of a special Ringer's solution. A heart so perfused may be likened to a machine working without lubricant, the normal lubricant being adrenin, which facilitates certain actions of calcium. Since blood contains adrenin and Ringer's solution does not the calcium tension of the solution must be higher than that of blood to compensate for the absence of adrenin. The fresh heart perfused with Ringer's solution beats at its maximum amplitude of contraction, but has a low order of "flexibility."—The Effect of Administration of Small Amounts of Thyroid Gland on the

Size and Weight of Certain Organs in the Male White Rat, by James Arthur Hewitt. In adult male rats administration of 0.1 g. or over of fresh thyroid per day causes hypertrophy of heart, liver, spleen, kidneys, suprarenals, and possibly the pituitary. The thyroid is diminished in size. The enlarged organs tend to resume normal proportions after resumption of ordinary diet.—The Influence of the Depressor Nerve on the Pulmonary Circulation, by E. Sharpey Schafer. That the pulmonary system is provided with vaso-motor nerves no longer admits of doubt, but differences of opinion exist as to their action on the circulation. The author's experiments were made on large rabbits anaesthetised with chloroform and under the influence of chloral. Excitation of the central end of the cut depressor nerve in the rabbit—vagi previously cut—produces dilatation not only of the systemic but also of the pulmonary arterioles, the latter effect being usually less pronounced than the former, though occasionally the reverse is observed. The depressor is singularly susceptible to mechanical stimulation, even gentle traction with a thread or the placing of the nerve on electrodes. During the inhibition of the systemic arterioles a large amount of blood is conveyed to the right side of the heart, and the same applies to the pulmonary arteries and the left side of the heart. In animals which, unlike the rabbit, do not possess a separate depressor but have depressor fibres included in the vagus, similar depressor effects are caused by stimulation of the central end of either vagus—both vagi being cut; but the results are apt to be complicated by other effects produced by stimulation of other afferent fibres in the vagus. Conspicuous Traube waves have been found sometimes to follow excitation of the depressor.—The Influence of the Respiratory Movements upon the Blood Pressure in the Pulmonary System, by E. Sharpey Schafer. By a special method described by the author the following, amongst other results, were obtained. Every inspiratory movement is accompanied by a fall of pulmonary blood pressure and every expiratory by a rise. These effects are purely mechanical and are due to increase in calibre of the pulmonary capillaries caused by inspiration and to their diminution by expiration. The changes of pressure in the aortic system caused by the respiratory movements are dependent upon those in the pulmonary system, but bear no constant ratio to them. Most frequently, however, the rise of aortic pressure is synchronous, or nearly so, with the inspiratory fall in pulmonary pressure, and a fall of aortic pressure synchronises with the expiratory rise. In the first stage of asphyxia inspiratory movements were found to increase in force, and expiratory movements to diminish—that is, the pulmonary pressure falls, whilst the aortic rises. In the second stage of accentuated expiratory movements the pulmonary pressure rises.—The other papers in this number are a Survey of Some Elements of Cardiac Excitability, by W. Burridge; Movements of Emotivity in a Japanese Subject, by A. D. Waller; and a Note on Cats with Double Vagotomy, by E. Sharpey Schafer. Two cats with double cervical vagotomy—one lived six months and the other four months, death being due to septic pneumonia, the result of the passage of food or vomit into the air-passages and lungs.

The Psychic Research Quarterly. London: Kegan Paul, Trench, Trübner and Co., Ltd. Vol. I., No. 1. 3s. 6d. net.—This new publication has been founded to supply the widespread demand for trustworthy information about psychical research, to counteract the inaccuracy and sensationalism of the lay press and the bias of the professedly spiritualistic journals. The first number certainly fulfils the editorial promise to give to its readers "every opportunity of forming their own opinions by publishing the best obtainable contributions to the problem from all sides." The first of these is an article on Scientific Method in Psychical Research, by Dr. F. C. S. Schiller, the well-known Oxford exponent of "Humanism." He points out that every problem of knowing is complicated by the presence of "bias," and that the topics of psychical research are peculiarly fitted to excite undue credulity or incredulity. From the point of view of science the existence of widespread bias hostile to psychical research has been the more important because it has led to the long neglect of this field of inquiry and to the scanty support which has been accorded to the pioneers who have tried to bring the methods of science to the solution of its problems. A plea is put forward for the endowment of psychical research; for here, as elsewhere, the secrets of nature are not to be wrested from her without much arduous and toil. Dr. Schiller believes that the only test that will be universally convincing in psychical research is the pragmatic test. It will be impossible to maintain an attitude of theoretic distrust if the beliefs arrived at can be applied to practical uses in the routine of everyday life. As an example of this he cites a document he once saw which greatly impressed him. It was a form of contract in which a firm of well-sinkers, who employed a

"dowser," were prepared to find water in a supernormal manner on the basis of "No water, no pay."—On this topic of water-finding Sir William Barrett contributes a very interesting article, The So-called Divining (or Dowsing) Rod, in which he describes some instances of successful water-finding which might have justified such a contract as that referred to by Dr. Schiller.—The only article which has a clearly spiritistic flavour is one by Mr. J. Arthur Hill on Further Evidence of Supernormal and Possibly Discarnate Agency. He tells how he began his investigations as a sceptic of the school of Haeckel and Huxley, but was forced to become a believer by the accumulation of data of which a spiritistic explanation seemed the only reasonable and logical one. The evidence capable of being presented in a magazine article cannot be expected to convince anyone, but it may serve to direct interested readers to the fuller reports given in Mr. Hill's published works.—Miss Lily Dougall, writing on Faith and Superstition, maintains that science has no test for what may lie behind supernormal experiences, and seems to hold the questionable doctrine that we should attribute no objective reality to any intellectual conception which is out of harmony with our fundamental faith about the universe. She is inclined to believe, as do many of those who take a practical interest in psychical research, that the ultimate value of modern spiritualistic speculation is the extension of human knowledge as regards the powers and capacities of the sub-conscious, which appear to develop under trance conditions.—Dr. T. W. Mitchell writes on the relations between Psychopathology and Psychic Research. He discusses the nature of the trance-state and the source of the supernormal knowledge which sometimes appears to be manifested therein. He points out that, while we have no experimental parallel for the simple alternating type of double personality, we have in deep hypnosis a close parallel in many respects with the phenomenon of co-conscious personalities. The psycho-analysis of mediums might lead to useful results, but opportunities for such exploration would be very limited. Dr. Mitchell suggests that much popular misconception would be avoided if the distinction between the mechanism and the supernormal content of trance communication were clearly kept in mind, and indicates how psychopathology may throw light at least on the data available for the investigation of psychical research problems.—Mr. C. A. Richardson examines Immortality and the Survival of Bodily Death as Philosophic Problems in the light of the metaphysical hypothesis upheld by him in his recent work, "Spiritual Pluralism and Recent Philosophy." He points out that the problem of immortality is on an entirely different footing from that of the survival of bodily death. The latter can only be settled by a consideration of the empirical evidence, much of which he is disposed to accept. He considers specially important the evidence obtained from automatic script when the medium is not entranced, and thinks it points very markedly in the direction of survival. His reasons for ascribing so much importance to this particular class of evidence are not very cogent.

Tubercle. A Monthly Journal Devoted to all Aspects of Tuberculosis. Vol. I., No. 11. August, 1920.—This number opens with Some Thoughts on the Treatment of Pulmonary Tuberculosis, by Dr. Clive Riviere, who maintains that sanatoriums have not failed, and that the hygienic-dietetic, or rather the rest-and-exercise treatment does, in fact, constitute a cure of proven value. Failure is attributed to delay in diagnosis and defects in after-treatment, not to any inherent fault in the methods of the sanatorium. On the question of the utility of graduated labour, as distinguished from walking exercise, in treating patients who will return to sedentary life Dr. Riviere considers further investigation necessary before a final opinion is formed. A discussion on chemotherapy by metallic agents brings an interesting paper to a close.—The relation of pregnancy to tuberculosis and the indications for abortion form the subject of several book notices and abstracts, while a critical review deals with the incidence of tuberculosis among the first-born and later children. It is concluded that the evidence points to some unknown congenital factor as the cause of the greater susceptibility of the first-born in adult life.—Another interesting review discusses the remarkable difference said to have arisen between the American campaign against tuberculosis and our own, the former being concentrated on improving the soil, while the latter is directed mainly to limiting the spread of the seed. This radical divergence of authoritative opinion should warn us against urging drastic or costly measures until experiment has proved their value on a small scale.

GREAT NORTHERN CENTRAL HOSPITAL EXTENSION.—The designs of Messrs. H. Percy Adams, F.R.I.B.A., and Chas. H. Holden, A.R.I.B.A., have been selected for the proposed extension of the Great Northern Hospital, Holloway.

Reports and Analytical Records

FROM

THE LANCET LABORATORY.

- (1) VACCINES; (2) ANTACID LOZENGES; AND
(3) FECTO DISINFECTANT.

(PARKE, DAVIS, AND CO., BEAR-STREET, REGENT-STREET,
LONDON, W.)

(1) A new series of vaccines introduced by the above firm and prepared under the control of the bacteriological authorities at St. Mary's Hospital calls for notice. First, is a diphtheria bacillus vaccine suggested for the treatment of diphtheria carriers and of convalescents from that disease; secondly, a mixed gonorrhoea vaccine prepared to meet the cases in which secondary infections arise; and, thirdly, an antirheumatic vaccine prepared from numerous strains of streptococci isolated from the mouth, intestinal and genito-urinary tract of patients suffering from rheumatism and rheumatoid arthritis. The suggestion is that such disorders follow streptococcal infections of these channels, and encouraging results are reported from the use of a mixed vaccine.

(2) We have confirmed the formula of these lozenges—bismuth carbonate and magnesium carbonate with essential oils of a well-known carminative kind. The combination is a good one, and the inclusion of taka-diastase, the activity of which in the hydrolysis of starch was shown in our examination, adds to its usefulness in dyspeptic troubles.

(3) Fecto, we find, is a clear, colourless solution of the alkaline hypochlorites, and the specimen submitted showed an available chlorine content of 4.6 per cent. It has a slight chlorinous odour, and its powerful disinfecting properties have been well established. Apart from surgical application, when suitably diluted (1 oz. to the gallon of water) it can be used generally and safely for domestic disinfecting and deodorising purposes.

(1) PERTONAL AND (2) BRUNOL.

(STRANGE AND GRAHAM, LIMITED, 50, CITY-ROAD, LONDON, E.C.)

(1) A contribution from the Pharmacological Laboratory, Cambridge, on pertonal, which is para-acetyl-amido-ethoxy-benzene, was published in the *Journal of Pharmacology and Experimental Therapeutics* of February, 1919, from which it appears that this substance possesses approximately one-half the toxicity of phenacetin, and as an antipyretic produces similar effects in doses approximately double those of phenacetin. It is reported also that the solubility of pertonal is 1 in 60, whereas that of phenacetin is only 1 in 1700, and while the latter synthetic exerts a directly depressant action on the heart, pertonal exerts a stimulation. According to these results the drug promises to prove a valuable analgesic, but further clinical evidence seems desirable as to its general effects. It is a white crystalline powder and shows a chemical composition related to phenacetin.

(2) Brunol is normal primary butyl salicylate, and the record of its application in the relief of burns is striking from the cases reported from Guy's Hospital. It is a highly refractive fluid immiscible with water, but yielding to that fluid some salicylic acid, as shown by the perchloride of iron test. In burns and scalds it is used as a dressing on lint. Whilst palliative and soothing, it is said to promote granulation and healing.

SEMPROLAX.

(THE WM. BROWNING CO., LTD., ALBERT WORKS, ALBERT-STREET, PARK-STREET, LONDON, N.W.)

The effectiveness of this emulsion is shown by the fact that, according to our examination, only 10 per cent. of the petroleum was directly extracted by petroleum ether. By subsequent chemical dislocation, however, we found present just short of 80 per cent. by volume of paraffinum liquidum of correct viscosity. The emulsion is, in fact, so perfect that it dilutes with water, still keeping its condition of emulsion. There is no separation of the hydrocarbon.

LECTONA.

(LECITHIN, LTD., RICKMANSWORTH-ROAD, WATFORD, HERTS.)

The claim made in regard to this preparation is that it contains lecithins and vitamins, and statements are made referring to the value of these substances. We have established in our analysis the presence of fatty substance which proved to contain phosphorus. It is a malted preparation, and, according to our results, contains 2.91 per cent. of fat. The fat extracted was yellow in colour and appeared to be of an egg origin. The food shows high protein value, equalling 8 per cent. of nitrogen. There are present also sugars derived from malt and milk. There was no starch present according to our examination.

GLAXO, NOS. 1 AND 2.

(GLAXO, 155-157, GREAT PORTLAND-STREET, LONDON, W.)

The introduction of two dried-milk products with an admitted reduction of fatty contents is of interest, inasmuch as some authorities on infant feeding take the view that a high percentage of fat in dried cow's milk causes disassimilation in certain delicate subjects. The samples submitted to us gave the following results: No. 1: fat, 14.40 per cent.; No. 2: fat, 19.60 per cent.—results which conform to the statements of the manufacturers. The reduction of fat in dried milk as here shown no doubt helps in preserving the product against getting rancid, which, it may be added, is a serious trouble with full-cream milk powder. Standard glaxo contains the whole of the cream and keeps well.

SKETOFAX.

(BURROUGHS, WELLCOME, AND CO., SNOW HILL BUILDINGS, LONDON, E.C.)

What is described as a new culicifuge has recently been introduced by the above firm. The preparation is founded on an oily basis resembling vaseline which is practically clear. It is contained conveniently in a collapsible tube. The composition has been well considered, and the essentials making it a sedative and a guard against the attack of malignant insects are of recognised value. It is useful to remember in this connexion that the sting of the wasp is alkaline, whereas that of the bee is acid.

CROFTOL.

(THE UNITED TURKEY RED CO., LTD., 46, WEST GEORGE-STREET, GLASGOW.)

This is a dark-brown, clear, syrupy fluid, containing, according to our analysis, a maximum of tar acids and a minimum of alkali to render them soluble. It mixes well with water, with a slight opalescence resulting. We found present 80 per cent. by volume of tar acids, and alkali equivalent to 4.4 per cent., expressed in terms of Na_2O . In view of the high proportion of tar acids it is not surprising to learn that the germicidal efficiency is high and 11 times that of carbolic acid itself. It shows an alkaline reaction, and when diluted as directed exhibits no corrosive action on the metal of surgical instruments.

SPASMALGIN (ROCHE).

(THE HOFFMANN-LA ROCHE CHEMICAL WORKS, LTD., BASEL; AND 7 AND 8, IDOL-LANE, LONDON, E.C.)

Spasmalgin is described as a combination of papaverine, omnopon, and atrinal, and is supplied in the form of tablets and solution for hypodermic injections, the administration of which, of course, is subject to the control of the physician. The chief claims for its pharmacological uses are that it is a soothing and sedative preparation in gastric pain, colic, and painful menstruation; in a word, an antispasmodic or analgesic. We are not aware that papaverine has been singled out as of special value, but the suggestion is of interest that as an alleviative it is without side-effects, aided by the complete constituents of opium (omnopon). Atrinal, a sulphonic derivative of atropine, is claimed to have a stimulating action on the respiratory centre, increasing not only the number but also the depth of respirations.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 4, 1920.

Modern Applied Physiology.

THE meeting of the British Association for the Advancement of Science at Cardiff last week was an agreed success, not so much in the numbers that attended as in the welcome revival of the opportunity of discussion in congress of scientific progress in many directions. Although regular meetings were suspended through the war period, it is evident from the papers read at the sessions this year that scientific thought was moving all the time even without the stimulating suggestion available at such gatherings. War, in fact, turned a searchlight to bear on many pressing problems, revealing where research was needed before the comfort, convenience, and necessities of human life could be secured in a stable form. We may be excused for seeing the greatest progress along the lines of applied physiology, and in this direction many of the more important addresses pointed. We referred last week to Professor W. A. HERDMAN'S address from the presidential chair, in which he pointed out the advantage to be gained from placing the harvesting of the sea on less empirical lines by studying more closely the habits, movements, diet, and growth of fishes. Professor J. STANLEY GARDINER, in the Botanical Section, touched upon the same subject of human nutrition in relation to the intensive cultivation of food in the land. He showed how capacious is the market for home produce. If only one-fifth of these requirements could be produced at home, this would amount in value to over 20 million pounds, requiring the use of several hundred thousand acres of land and providing employment for 100,000 men.

The address of the President of the Physiological Section also dealt with physiology as applied to large masses of humanity. We print Mr. J. BARCROFT'S study of anoxæmia at the front of THE LANCET this week. Starting from what appears to be only a careful study of the gases of the human blood, particularly with regard to its oxygen content under varying environments, the plot develops from mountain climbing as a hobby to encompass the saving of countless lives risked in gas warfare and the safety and comfort of airmen, military and civilian. The lessons of gas warfare, and the entrancing history of the developments of counter measures are drawn also in an annotation in our present issue dealing with the work of the Royal Army Medical Corps. In the same section Dr. THOMAS LEWIS proposed to bring physiology still more closely home in the medical curriculum by turning the student's observation upon the human organism rather than upon the body of the lower animals. Although it was true that the largest part of our knowledge of human function was still derived by analogy from animal observation, he was concerned rather that students should, in the most impressionable period of their career, learn how to investigate the human body itself. Papers read in other sections bore on this thesis. Professor KARL PEARSON in his Presidential address to the Anthropological Section held that

the pulse-tracing, the reaction-time, the mental age of the men under his control were far more important to the commanding officer, and indeed to the employer of labour, than any record of span, of head measurement, or of pigmentation categories. To-day psycho-physical and psycho-physiological characters were of greater weight in the struggle of nations than physique and stature. The experience of the war bore out the need for a new anthropology founded on psychometry. In his address to the Subsection of Psychology on the dreams of children who are physically defective, Dr. C. W. KIMMINS brought out the conclusion that these dreams differ from the normal in several instructive ways which have a practical bearing on educational method.

This is in barest outline the message of the British Association of 1920—a recognition of the application of the principles of physiology to the smallest speck of living matter and to the largest problems of human life. Cardiff itself afforded, however, during the session a curious instance that something still remains to be achieved in the application of orderly scientific method to human requirements. Electric power was there ready harnessed to man's use; all the apparatus of refuse destruction were to hand in working order. But traffic was stationary, and dirt accumulated in the streets from failure of the human element in the machinery. The applied physiology of industry is still in its infancy, and until it is better understood the application of much else will be liable to miss. A successful solution of the problem of industrial fatigue and the adaptation of industry to environment would tend greatly to the advancement of science, and form worthy subjects for the attention of the British Association.

Death Registration.

ALL is not well with the existing arrangements for recording the fact and the cause of death, matters of importance alike from a social and a scientific standpoint. The deputation from the British Medical Association and the Medical Parliamentary Committee, which waited recently¹ upon the Home Secretary and the Minister of Health, laid before them certain recommendations for the amendment of the law in these respects and in the manner of holding coroners' inquests. Other organisations are dissatisfied with the position. At the annual meeting in Birmingham of the Royal Sanitary Institute Alderman J. R. HURRY, honorary secretary to the British Undertakers' Association, commented on the dangerous defect of the present system in regard to the registration of stillborn children. The questions thus raised must be considered in the light of the report published by the Departmental Committee, over which Sir MACKENZIE CHALMERS presided in 1909. Death certification is closely bound up with the coroner's functions, and the two will have to be considered together when Parliament finds the opportunity, long overdue, of dealing with the recommendations of the Departmental Committee and the fresh points which have arisen during the ten years since its Report was issued.

Both the medical deputation and the undertakers' representative emphasise the importance of certain recommendations of the Committee. For example,

¹ THE LANCET, August 14th, p. 375.

a medical practitioner should have to state on his certificate that he has satisfied himself by personal inspection as to the fact of death; again, the absence of a medical certificate should invariably be reported to the coroner. The law as it stands offers every opportunity for premature burial and every facility for the concealment of crime. The case of those who urge amendment could hardly be put more strongly than it is thus put by the Departmental Committee. The deputation, however, breaks new ground in submitting a demand for a dual form of certificate: one part, certifying the fact of death, to be given to the relatives of the deceased, and the other certifying the cause of death, to be handed only to the proper authorities, presumably the Registrar. It is intended that the latter document should be treated confidentially, as the reason given for its use is that under the present system relatives are informed of details which it is not necessary, and at times very inadvisable, for them to know. This, the Home Secretary was informed, leads to the employment by the certifier of euphemisms which deprive the statistical returns of any real value. While the motive of the suggestion is sound enough, the proposal itself amounts to keeping surviving relatives in ignorance of the cause of death as certified. It is hardly likely that the thoughtful part of the public would sanction such an innovation, and we believe that practitioners themselves would sometimes find it prejudicial to their interests. The fact that there existed a secret certificate, possibly varying from the statement made to the family of the deceased, might well tend to diminish confidence and impair friendly relations. Parliament would require strong evidence of the advantages to be gained from this suggestion, and of the weight of medical opinion in its favour, before adopting it. The most drastic proposal of the deputation was to the effect that the coroner's functions as we are familiar with them should be done away with, and his duties restricted to determining the fact and nature of death, leaving the magistrates to carry on the inquiry where it was "proved to be a case for legal intervention." Mr. N. BISHOP HARMAN, the principal spokesman of the deputation, said that the legal side of the coroner's work seemed unnecessary and the publicity of his court undesirable, and Mr. E. B. TURNER, who supported him, referred to the inquest as a pseudo-trial, often conducted without due regard to the laws of evidence.

These are important matters which were not considered by the Departmental Committee of 1909. Probably a second Committee with an enlarged reference might usefully carry on the work of its predecessor as a preliminary to legislation, which should then be introduced without delay. Such a Committee would not necessarily take long to inquire and report, as a great deal of historical matter and questions not needing to be reopened were dealt with by its predecessor. It would have before it the evidence already given for comparison with that advanced in favour of the views of the deputation. It could recall witnesses heard before and ascertain whether they had changed their opinions in the years that have intervened. It could consider afresh questions of fees for medical witnesses and many other matters in the light of present-day conditions. The progress of scientific medicine will be seriously impeded unless these things are cleared up and cleared up promptly.

The Prevention of Tetanus.

THE Research Defence Society has done well in publishing an authoritative pamphlet¹ by Sir DAVID BRUCE on the prophylactic and curative use of antitetanic serum during the late war. The main object of the pamphlet is to place before the public in a clear and convincing manner some facts which may help to discount the machinations of antiscientific fanatics, and in this object Sir DAVID BRUCE will admirably succeed if his pamphlet obtains a wide enough circulation. The sequence of events in the growth of our knowledge concerning tetanus and its culmination in the wholesale use of antitetanic serum during the war, which finally reduced the incidence of tetanus to almost negligible proportions, form a particularly clear-cut demonstration of the value to mankind of the experimental inoculation of animals. Outside the numerically small circle of doctors and nurses few can have seen in his agony a man suffering from tetanus, and Sir DAVID BRUCE rightly insists on the appalling horror of the disease. It is demonstrably fair for defenders of research thus to call true sentiment to their aid.

The facts brought forward by Sir DAVID BRUCE have been published at various times in our columns and in broad outline at all events they are well known to every member of the medical profession. Many of those who served in the R.A.M.C. during the first months of the war had too many opportunities of gaining first-hand knowledge of the disease. Later, when the prophylactic routine for gunshot wounds had been established, these opportunities became rarer, though the slow realisation of the danger of tetanic infection from lesions so trivial as blistered or frozen feet maintained the incidence at a higher level than would otherwise have been the case. Thus there was a considerable recrudescence of the disease in the winter of 1916-1917, when the incidence rose to nearly 3 per 1000 casualties in the home hospitals. In June, 1917, the prophylactic routine was further extended, so that thereafter every casualty received four injections of serum at intervals of a week, and the incidence then never rose again as high as 2 per 1000, not even during the retreat in March, 1918, when external conditions greatly favoured an increase. During the heavy fighting in the last four months of the war the incidence remained below 1 per 1000—a striking contrast to the nine-fold figure registered in September, 1914.

Nevertheless, our memories are short, and it may be doubted whether even the medical profession has fully taken to heart all the lessons learnt during the war. Any prophylactic routine can be enforced with the help of military discipline, but in civilian life there is no such perfect coördination, and it is something of a reproach to medicine that prophylaxis against tetanus has not been more generally applied during the last two years. Tetanus is admittedly not a common disease in civil life, but it continues to occur in spite of our ability to make it almost unknown. Publicity was given recently in the columns of the *Times* to inquests held at Greenwich on one day into two cases which had died from tetanus at

¹ The Prevention of Tetanus during the Great War by the Use of Antitetanic Serum, by Major-General Sir David Bruce, K.C.B. F.R.S., Army Medical Service, Chairman of the War Office Committee for the Study of Tetanus, 1914-1918. London: Geo. Poulman and Sons, Ltd. Pp. 27. 1s.

different hospitals. No reference was made in the report to the use of prophylactic serum, and it is possible that in one case, in which a man had trodden on a nail protruding from a plank of wood, no medical advice was obtained until the symptoms of tetanus appeared. In the other case a boy had severely injured his finger in the iron grating of a street gully, and prophylactic serum should undoubtedly have been given. The preventive routine can and should be enforced by the authorities of every hospital as rigidly as it was in the army, and the attention of the Ministry of Health might be directed to the desirability of securing this. Meanwhile Sir DAVID BRUCE's excellent pamphlet may serve to emphasise to the public and to the medical profession alike the great importance of efficient prophylaxis. To the latter it may also suggest the necessity for becoming familiar with the principles of the intensive treatment of the disease, when once established, by the intradural injection of the concentrated serum—a method in use during the last year of the war. Sir DAVID BRUCE admits that there has never been any uniformity of treatment; on general principles it is reasonable to suppose that so fatal a disease is best combated by the most drastic remedy.

Annotations.

"Ne quid nimis."

THE PERMANENT INTERNATIONAL HEALTH OFFICE.

WE recently noted with satisfaction the adoption by the Council of the League of Nations, lately held at San Sebastian, of the establishment of a permanent international health bureau as part of the organisation of the League. This will incorporate and supersede the International Office of Public Hygiene in Paris, set up under the Rome Convention of 1907, and usefully active within the limited scope of its constitution. Formal adoption of the enlarged scheme by all the nations in the League cannot take place until November, but there is no reason to doubt that the functions of the Health Office will be extended in the sense of the Council's recommendations. The permanent committee of the Health Office will advise the League in all matters affecting health. It will help to bring administrative health authorities throughout the world into closer relationship, and to secure international agreement on matters of health where common or standardised action by different Governments is needed. It will aim at organising rapid interchange of information in face of epidemics which demand immediate precautions. In dealing with the protection of the worker against sickness, disease, or occupational risk the permanent committee will coöperate with the International Labour Organisation in securing action; doubtless many opportunities will occur of conference and coöperation with the League of Red Cross Societies. One of the most practical functions of the permanent committee will be to organise missions on matters of health at the request of the League of Nations. This is a general outline only of the work of the International Health Office, which will not be limited by any cut-and-dried scheme. Its chief promoters have in view a useful and practical piece of health organisation. One of its first tasks might well be to adopt an international code of disease nomenclature, without which it is difficult for the nations of the world to communicate intelligibly on health affairs. If only international organisations had come into being at a time when Latin was still the medium of civilised intercourse it would have been easier.

GROWTH AND METAMORPHOSIS.

RECENT investigations have shown that not only growth but development and metamorphosis are gradually being brought within our control, and that all three phenomena may be modified in various ways and are probably due to different causes. The marvels of internal secretions and the mysteries of "interstitial glands" are frequently paraded in the lay press, while "growth vitamins" are beginning to be part of every man's general knowledge. There are some recent advances in these matters to which we wish to direct attention, more especially as to endocrine balance and certain special endocrine activities. Animals whose full development implies metamorphosis present problems different from those arising from the regular orderly growth of animals not undergoing metamorphosis. New factors come into play and require study and explanation. If to the ordinary food of frog-tadpoles or other larval amphibians, such as salamanders or the axolotl, thyroid extract or thyroid tissue be added, it is known that the duration of the tadpole stage may be greatly shortened, even to one-fourth of the normal period. Frog-tadpoles under appropriate conditions may become frogs in three weeks instead of three or four months. This is not the realisation of an elixir vitæ, but the acceleration of "ageing" as described by Gundernatch in 1912—an "ageing" transformation since confirmed by many observers. The thyroid causes a precocious development of the body, but suppresses further growth. R. K. S. Lim, in a recent paper published in the *Quarterly Journal of Experimental Physiology* (see p. 504 of our present issue), has added to our more intimate knowledge of the histological changes that occur in thyroid-fed tadpoles of the common frog. The number of mitoses in tissues generally and blood cells is increased and the organs become more adult in character. Metamorphosis is accelerated, rapid absorption of the tail muscles occurs, and normal processes are hastened, so that a nine days' tadpole is histologically more adult than a non-treated tadpole of 20 days. Such is the speeding-up or "age-acceleration." The effects of the suppression of thyroid activity in larval amphibians by cauterisation or excision are the converse of those obtained by feeding with thyroid, the tadpoles being prevented from undergoing full metamorphosis. This stage cannot be regarded as an elysium of perpetual youth, for the victims are condemned to live on a lower platform of existence. If thyroglobulin is hydrolysed a mixture of iodised aromatic amino-acids—iodothyron—is obtained; this has some thyroid-like activities, and so, according to Abderhalden, have artificial iodised proteins, biuret-free products obtained from thyroid substance. All of these possess accelerating action on the metamorphosis of tadpoles; certain iodine-free bodies are said to have such an action. According to Abderhalden, extract of thymus or adult thymus substance prevents metamorphosis but not growth, an action exactly opposite to that of thyroid. We know that the removal of the thymus in mammals arrests growth of the sexual glands, and the bones especially present appearances not unlike those occurring in rickets. E. Uhlenhuth, of the Rockefeller Institute, has carried the matter a stage farther, experimenting on two species of salamanders. According to him, metamorphosis of the larvæ into adult animals takes place only when the thyroid gland begins to excrete the thyroid hormone. Many larvæ with fully developed thyroid glands do not undergo metamorphosis, and since the follicles of their thyroids contain large quantities of "colloid" for a considerable time before metamorphosis, it is probable that the thyroid gland cannot begin to excrete its hormone unless a second factor is present in the larvæ. This factor, it seems, is elaborated during the process of growth, and must be present in a sufficient quantity in order that the thyroid function may begin. The greater the rate of growth the shorter is the length of the larval period. Metamorphosis thus depends not only upon the thyroid hormone, but also on a second substance the quantity of which increases in the same ratio as growth. This second substance must be present

in a certain quantity in order that metamorphosis may take place, and its rate of formation for the same kind of food and for the same rate of growth is distinctly influenced by two factors, the quantity of food and by the temperature. It is quite clear that we are a long way from a satisfactory explanation of the very far-reaching, varied, extensive, and pre-eminent influence of the internal secretion of the thyroid gland on growth development and general metabolism. Nor do we know much of the interdependence of that strange physiological triad—the thyroid, pituitary, and adrenal glands.

DR. COWLEY AND DR. CAWLEY.

SOME medical men are born poets, whereas few established poets are made doctors of medicine. A striking example of the latter select group is to be found in Abraham Cowley (1618–1667), of whose poetry and somewhat wistful charm there is a brief but polished appreciation in the September number of the *Ninth Century and After*, without, however, any suggestion that he belonged to the healing profession. This omission, if such it be, is natural enough, for he was created M.D. at Oxford on Dec. 2nd, 1657, by edict of the Government, in order, so his biographer Sprat considers, to serve as a blind for his real designs—namely, those of a Royalist agent. At any rate, it does not appear that he ever published anything medical, and he certainly should not be confused with Thomas Cawley, often incorrectly quoted in the literature as Cowley, who in 1778 by giving a careful account of a single case earned the credit of the first description of diabetes due to a pancreatic lesion. The case was one of chronic pancreatitis with numerous calculi not larger than a pea. Cowley was a scholar of Trinity College, Cambridge, where, about 1639, among other poems, he wrote an elegy on the death of his intimate friend, William Harvey, who must not be thought to be the discoverer of the circulation (1578–1657). Though if the dates are not kept in mind this error would be excusable, for Cowley was ejected from Cambridge in 1643 and took refuge at Oxford, where he might have come in contact with the King's physician who became Warden of Merton in 1645, and travelled much on behalf of the Royalists. He was also one of the original members of the Royal Society and composed an ode to it. Although, as H. H. Bellot says in the article we have mentioned, "at a precociously early age Cowley fell in love with the delights of simplicity and quiet" he had an unfair share of the alarms and excursions of civil war and of political intrigue. It is satisfactory to learn that he obtained a quiet retreat in the country, though only four years before his premature death, and there composed some essays modelled on Montaigne's. His confession, "I love Littleness in all things—a little convenient Estate, a little cheerful House, a little Company, and a very little Feast," may remind the reader of Professor A. E. Boycott's attractively whimsical contribution to the Osler Volume, entitled "On the size of things, or the importance of being rather small."

DEFENCE AGAINST GAS WARFARE.

THE whole question of defence against gas warfare is instructively reviewed in an address by Lieutenant-Colonel P. S. Lelean, published in the June number of the *Journal of the Royal Army Medical Corps*.

It was, he says, on April 23rd, 1915, that London got the news of the first gas attack. The War Office at once made urgent demands on the R.A.M.C. for protection, and that these demands were met was due largely to the high scientific attainments and unfailing resource of Colonel Sir W. Horrocks. The gas first used was chlorine. Its menace was met with pads of cotton waste soaked in glycerine and hyposulphite of soda, sewn into muslin bands. It took time to plan, to obtain and assemble materials for these pads, and to organise their manufacture, but in 60 hours there were 98,000 at the front, in a week 300,000, and in a month 2,000,000. These pads would only neutralise gas for ten minutes, and a man could not work in them for long. The pad was replaced by a helmet made of cotton stuff. It was difficult to get suitable fabric and dyes; eyepieces had

to be fitted and carbonate of soda had to be added to the "hypo" to deal with sulphurous acid, yet in three weeks 300,000 were issued, and the work was so well done that the next gas attack, which lasted four hours, did not cost us one life. But more complicated gases came later, and protection against every possible gas had to be provided. The best absorbent for each gas had to be found, and the gas was then tried through an impregnated helmet on a rat. The next experiment was made on a pig wearing a helmet, and if the pig survived one hour the gas was tried on one of the staff, wearing a helmet, in what was called "the lethal chamber." Scientists with dogged courage risked themselves in these dark chambers, became incapacitated, and returned to the adventure as resolute as ever. When the number of gases increased the number of absorbents had to be increased too. Sodium phenate was an effective absorbent for carbonyl chloride and hydrocyanic acid, but the first day helmets were dipped in this solution 200 women had their arms burnt, a horrid shock to the directors. Then it was found that the sodium phenate having absorbed the hydrocyanic acid, the compound became broken up by the carbonic acid of the breath and the rats died; so an exit valve had to be fitted to the helmet through which expired air must escape. Then hexamine (urotropin) was found by a Russian to clear the air of these gases, and for a time a ton a day of urotropin was made for this purpose. These helmets were on issue from July, 1915, to February, 1918, and in all 26,800,000 were made. Effective goggles, too, had to be invented as a defence against lacrymatory gas (benzoyl chloride). Not only men but horses also were protected. Indeed, one pig wore a helmet through a gas attack on Dec. 22nd, and was saved to appear at dinner on Christmas Day as roast pork. The helmets were insufficiently "polyvalent," so were replaced by the box respirator, in whose "tower" were half-a-dozen trays of various absorbents, separated by cellulose diaphragms, and including, in addition to "hypo," and soda, soda lime permanganate to deal with arseniuretted hydrogen (the soda lime permanganate in granules was invented by the late Lieutenant-Colonel E. F. Harrison after 48 inconclusive experiments), sodium sulphite against chlorpicrin, and animal charcoal. The box withstood six gases run through it in succession for one hour each. This respirator, though so complicated, took only 25 seconds to put on, and 16 millions were issued.

This very brief résumé of the address given by Colonel Lelean can hardly do more than call attention to it; those who read the original will be impressed with the urgent gravity of the calls made during the war on our resourceful scientists, and by the tremendous scale of the work that had to be undertaken at a moment's notice. Colonel Lelean remarks that Germany had ever boasted of her "better brains," but once they challenged our scientists squarely and thoroughly woke them up it was our men who won at every turn. He is to be congratulated on his clear and comprehensive account of this scientific victory, for which the army has indeed every reason to be grateful to the Royal Army Medical Corps. We may add that amongst those who with "dogged courage risked themselves in these dark chambers," and who "became incapacitated and returned to the adventure as resolute as ever," was an assistant from THE LANCET Laboratory. On regaining consciousness he said, "This helmet is no good!"

TUBERCULOSIS IN CORSICA.

IN his inaugural thesis Dr. François Serpaggi¹ shows that in spite of the healthy climate tuberculosis is very prevalent in Corsica, perhaps even more so than in many other French departments. He attributes this occurrence to three principal causes—namely, malaria, alcoholism, and consanguineous marriages. The whole of the sea coast, especially on the east, as well as the neighbouring regions up to an altitude of about 300 metres, is infested by malaria. All forms of the disease are met with, benign tertian being the most frequent. The prevalence of malaria is attributed by the writer to the return of numerous soldiers who had contracted the disease in the East. Alcoholism, and especially the consumption of absinthe, is widely spread throughout Corsica, even in the smallest villages. The inhabitants, who were formerly very sober, gave way to alcoholism some time before the war owing to the introduction of cheap alcoholic liquors. It is

¹ Thèses de Paris, 1919–20, No. 181.

therefore not surprising to find that tuberculosis in Corsica, as in Normandy and elsewhere, has gone hand in hand with alcoholism. Dr. Serpaggi states that infection chiefly takes place in the school where there is a complete absence of hygiene and no measures are taken to exclude tuberculous pupils. In some cases families are infected by soldiers who have been discharged from the army for pulmonary tuberculosis. The disease also appears to be spread by milk and butcher's meat, there being no meat inspection in Corsica, except at Ajaccio and Bastia. Lastly, the large number of dark, damp, and generally insanitary houses is an additional cause of the prevalence of tuberculosis in the island.

NATIONAL HEALTH INSURANCE IN SCOTLAND.

THE administration of National Health Insurance in Scotland during the years 1917-19 is dealt with in a White Paper just issued. The report states that the number of Approved Societies for health insurance purposes was 245 in 1919, compared with 312 in 1912. The total number of Scottish cards in August, 1919, was 1,275,029. In an outline of the history of health insurance in Scotland since its commencement in 1912 to the present day, the report acknowledges that when the Act first became operative it was unpopular with both employers and employed. It had been made the occasion of an intensely hostile campaign, which had created an attitude of mistrust, in connexion with which the antagonism of the medical profession was an important consideration. From the outset, however, the general attitude of the Scottish people was one of acceptance. Actual opposition occurred mainly in farming and fishing communities, especially the former. Definite resistance, however, only materialised in certain agricultural counties, in which both employers and employed made common cause. The attitude of the farmers strongly affected that of the tradesmen in the smaller towns and villages dependent upon agriculture. In the Highlands and Islands there was strong dislike for the Act, due largely, no doubt, to the small number of people in these areas employed under contract of service. There was little active resistance, but the definite opposition manifested in other areas continued for years, and was only worn down by great patience and hard work on the part of the Commission's inspectorial staff.

At the outbreak of war the great majority of the difficulties had been overcome, and the Commission had been able to consider seriously the problems of improved services and extension of benefits. Now that the difficulties of the war period have been successfully passed, the value of health insurance to the community can be developed upon a secure basis. The creation of the Scottish Board of Health is a first and necessary step to this end. The Commission hopes that the Board will find in the existing insurance machinery a foundation upon which the future health administration of the nation can be built up and improved. About 95 per cent. of the irregularities disclosed by inspection consist of late stamping of cards, the agricultural community and small employers being the principal offenders. Seven years' experience has shown the original machinery to be remarkably complete, but the insured person is still apt to realise his place in the scheme only when he requires benefit. Some societies interpret their rules in a way which, considering the ignorance of many of their members, can only be described as harsh. The collection of contributions by the stamping of contribution cards has proved satisfactory. The feeling against compulsory insurance has greatly diminished. The desire to remain outside the Act has rather been replaced by a desire to come within its scope and thus profit by its benefits. The only sustained criticisms are as to the sufficiency of the money benefits and the method of raising the funds required. There is little doubt that the money benefits have been very helpful to sick persons, though complaints have been received that in many cases too much of the money has gone to the doctor or the midwife. Medical benefit has been found to work well, even under the

restriction of service necessitated by the war, and very little reliable evidence has emerged of neglect of duty on the part of insurance practitioners in support of loose general charges of inefficiency. There is, however, a feeling prevalent that certification of illness has not been performed with equal care by all practitioners. The Commissioners think there is reason for uneasiness, and share the general opinion that medical referees should be appointed to whom claimants could be referred.

With regard to the treatment of cases of tuberculosis, the Commissioners say that under the conditions of war these methods have had no chance of showing what their value really is. The Insurance Act has greatly stimulated the activities of local authorities in dealing with tuberculosis as an infectious disease. Should there come into existence a better organisation of local authorities many difficulties will be removed and the outlook will become more hopeful.

ANIMAL CASUALTIES DURING THE WAR.

THE recent war has demonstrated above all previous ones the economy of an efficient veterinary service for the care of animals both in health and disease, and the value of modern veterinary hygienic and preventive measures. The interesting and hitherto unpublished statistics compiled by the Veterinary Section of the Imperial War Museum (now at the Crystal Palace) show the totals of the British Army animal casualties throughout the war; these work out to less than 15 per cent. per year of the total number of animals on service, and are the lowest figures recorded in any campaign. Actually 484,143 animals lost their lives, including 5589 lost at sea through enemy action, and 22,812 camels (out of a total of 120,013); the percentage of mortality amongst camels was much higher than that amongst horses and mules. The fact that only 1.06 per cent. of the total animals shipped perished on the voyage is a great tribute to the efficient veterinary inspection before shipping and during the voyages, and the hygienic arrangements on board. To the Veterinary Service in particular must credit be given, for only those who have had experience in remount work and the purchasing of large numbers of animals, collected together from all parts of the earth, can know the chaos and risk of working without the skilled veterinary surgeon. Without his aid the most expert layman is soon lost in a tangle with mange, glanders, strangles, contagious pneumonia, epizootic lymphangitis, and a host of other contagious diseases, not to mention defects of wind and locomotion which speedily render the animals valueless for army work. In 1914 the average animal strength was 204,628, with 15.23 per cent. of sick, whilst in 1915, 1916, and 1918 the sick average fell to slightly over 10. Even in that terrible year, 1917, it only rose to 11.44, there being then 966,840 average strength, with 110,632 sick patients. The system of veterinary organisation to keep the animal army fit, and to deal with the sick in such a way that they were not an encumbrance, was well thought out and modelled on lines largely similar to those dealing with sick and wounded men. Veterinary officers at the front were concerned with prevention and first-aid only, the sick being collected in small groups and sent to the mobile veterinary sections, which units forwarded them to the very large hospitals down the line; these latter often contained between 3000 and 4000 patients each. Each sick animal on its way to the base passed through a Reception Hospital, where it was tested with mallein against that scourge of former armies, glanders; it was carefully inspected and treated for mange, ulcerative lymphangitis, influenza, and any other contagious ailment; the badly wounded received urgent aid; severe cases of debility were relegated to special hospitals; and the animals were grouped and arranged in batches according to their ailments. To the student of comparative medicine (and this section will soon include all medical men now that so many diseases have been proved transmissible from animals to man) the Veterinary Section of the Crystal Palace Imperial War Museum will prove of more than

passing interest. It illustrates graphically by means of photographs, models, war relics, and paintings (done by members of the Royal Army Veterinary Corps, amongst whom were voluntarily enlisted some of our best known animal painters) exactly how our sick and wounded animals were cared for on the battlefield and in hospital. Our veterinary colleagues earned well the title of "Royal" Army Veterinary Corps, conferred in recognition of good work. We congratulate them, not only on the title, but on the record of the British Veterinary Service.

BENZYL BENZOATE FOR PERSISTENT HICCOUGH.

SOME years ago Dr. David I. Macht announced the discovery, made in the Pharmacological Laboratory of the Johns Hopkins University, that the benzyl esters, particularly the benzoate, have a remarkable power of allaying spasm in unstriated muscle. In the *Medical Record* of July 24th he has described an important therapeutic application of this fact. He, as well as a number of practitioners who have communicated with him, have found benzyl benzoate of value in the treatment of hiccough—not only the mild forms so common in infants, but those forms which may be termed pernicious, in which the hiccough lasts for days and is unaffected by any kind of medical treatment, internal or external. The following are some examples:—

A man, aged 28 years, complained of persistent hiccough, which had continued for 24 hours in spite of the ordinary treatment. He was given a 20 per cent. solution of benzyl benzoate and ordered to take 25 drops in water every four hours. One dose was sufficient to stop the hiccough.

A man, aged 64 years, came under the observation of Dr. B. Sachs at the Hebrew Hospital, Baltimore, suffering from persistent hiccough of several days' duration which could not be relieved in any way. In the hospital various external applications, such as mustard plasters, were tried without success. Then medicine was given internally, but neither bromides, Hoffman's anodyne, morphine, nor any other drug gave relief. After taking a few doses of benzyl benzoate he was completely cured.

A woman, suffering from post-operative hiccough, was treated ineffectually with all ordinary drugs. The condition lasted over a week and she hiccoughed sometimes as often as 6 to 18 times a minute. Under benzyl benzoate she was relieved within 12 hours.

Dr. Macht also suggests that benzyl benzoate may be of diagnostic value in differentiating hiccough of purely central origin from that of peripheral origin. As the chief effect is on smooth muscle he thinks that the drug will be most useful in hiccough of peripheral origin. He finds that the most convenient method of administration is the one originally described by him. Benzyl benzoate acts best when given in a 20 per cent. solution in alcohol. Of this solution the patient takes 20 to 40 drops in water or milk. Dr. Macht has not found it convenient or advantageous to administer the drug in suspension in elixirs or syrups, and administration in capsules has produced irritation in some cases and rendered the therapeutic action too slow in others. To children the solution can be conveniently administered in sugar, water, or milk.

HOW TO TACKLE NERVE INJURIES.

THE committee appointed by the Medical Research Council to report upon injuries of the nervous system has brought in its findings¹ on the diagnosis and treatment of peripheral nerve injuries, and these will be endorsed by most surgeons who have had experience of such injuries in the great war. Before discussing the indications for and against operative treatment the report describes the various methods of testing nerve function with useful reference to the proper methods, the errors that may be made, and the "trick" movements which may deceive the investigator. Postural and nutritional treatment are then considered in their application to cases under observation in whom operative treatment is contra-indicated. In discussing the technique of operative treatment stress is laid on the necessity of conducting the operation as far as

possible in a bloodless field, but exception is taken to the tourniquet on account of the oozing likely to take place afterwards. End-to-end union is insisted on as the only sound method where a portion of nerve trunk is irreparably damaged; flap operations, implantations, and transplantations are all condemned. Surgical opinion in general has been coming round to this view. Under the various nerve headings methods are described whereby such end-to-end anastomosis may be obtained. Fine linen thread or silk is recommended for suture material in anastomosis, less fibroblastic reaction occurring than when catgut is utilised. A useful section is devoted to the signs and symptoms pointing to functional recovery, and some effort has been made to investigate the rate of recovery according to the particular nerve injured. The committee finds that the interval between the wounding and the operation has no influence on the time taken for recovery, a statement of practical value if only by exercising a deterrent influence on hasty surgery. Every case of nerve injury requires careful observation and probationary treatment. Pain, more especially that known as causalgia, receives due consideration, and stress is laid on the psychological factor; the surgeon is not all-important, the patient must assist. Causalgia has been the despair of many a surgeon, but clear indications are given in the report as to when and how he should act, and in what manner he can obtain the coöperation of the patient. Finally, the more important peripheral nerves are considered in turn, indications being given for treatment, and special hints for difficult and complicated cases. The report may be regarded as a valuable addition to our knowledge of nerve surgery, for which the committee deserves our thanks.

"THE HOUSE-FLY AS A DANGER TO HEALTH."

A PAMPHLET by Major E. E. Austen bearing this title is being sent to all medical officers of health, who are invited to purchase further copies (3d. each) for local distribution to officials. In a brief explanatory note attached to the pamphlet the Chief Medical Officer to the Ministry of Health points out that the education of the public in the life-history of house-flies and the most effective ways of destroying them forms an important part of the preventive measures required to combat epidemic diarrhoea and other fly-borne infections. The excellent plates forming the frontispiece show the house-fly proper and certain other species more or less harmful with which it is often confused. Certain common errors as to the power of growth and habits of the house-fly are exposed. For example, a small fly in the house is not a young fly in the sense that it will grow larger, since the fly emerges from its pupa-case full grown. Again, those who regard heaps of stale horse-manure as potential breeding places are reassured, and are advised to concentrate on the covering, close-packing, or turning over the surface of dumps of less than 24 hours' standing, since these alone attract ovipositing flies. Turning over the surface checks breeding, because the excessive heat generated by the fermenting manure lower down in the dump kills the eggs. Traps for the slow-moving maggots and methods of destruction of adult flies (which can lay eggs within three weeks after the deposition of the eggs from which they themselves are developed) are described, but it is once again made obvious that the most rational way of dealing with the pest is to attack the breeding places. The pamphlet (No. 1 of a series) is concerned only with the problem of house-flies within the British Isles, but an expanded pamphlet (No. 1A, price 1s. 6d.), which treats the subject more exhaustively, can also be obtained from the Director, British Museum (Natural History), Cromwell-road, London, S.W. 5, as well as those on lice, fleas, mosquitoes, bed-bugs, and other insects and vermin.

REVERSION OF £13,000 FOR SHEFFIELD HOSPITALS.

—Mr. E. Gamble Whiteley, of Sheffield, who died on March 25th, in his will, after making certain provisions for his widow and others, bequeaths the final reversion of his property, valued at £13,000, to the Sheffield Royal Infirmary, Sheffield Royal Hospital, the Jessop Hospital for Women, and the Sheffield Children's Hospital.

¹ Medical Research Council Report No. 54.

A PLEA FOR SIMPLE ANATOMICAL NAMES.

BASED ON THE FREE USE OF THE NATIONAL
LANGUAGE.

BY WM. CUTHBERT MORTON, C.B.E., M.A. (CLASSICAL
FIRST), M.D. EDIN.,

HONORARY DEMONSTRATOR OF ANATOMY IN THE UNIVERSITY OF
LEEDS; LATE CAPTAIN R.A.M.C., IN CHARGE OF THE DEPART-
MENT OF MUSCLE RE-EDUCATION, 2ND NORTHERN
GENERAL MILITARY HOSPITAL (ORTHOPEDIC).

I.—Foreword.

In a paper such as this it is useless to weigh the merits, absolute and relative, of the British and the Basle terminologies. Assuming that the British is as unsatisfactory as the supporters of the Basle claim, and that the Basle is as intolerable as those of the British claim, and that the two are as incompatible as everyone claims, let us see what can be done by simplicity and the free use of the national tongue. Such a change would, of course, in no way check the use of Latin by any who might choose it. On the contrary, the simpler the national names the simpler would the international be, and the more direct their appeal.

In the past emphasis has always been laid on the need for an international list in which "Each part shall have only one name" (B.N.A.), and on the need for national description to use only the international names, but if anatomy is ever to become a live subject it will not be by any fetish worship of dead languages but by each man speaking in his own tongue, using Latin and Greek only where his own tongue fails, and even then only in their simplest forms. It is true that for comparison and verification every structure must have an international label, and although the B.N.A. insists that "The terms shall be merely memory signs, and need lay no claim to description or to speculative interpretation," it is, on the contrary, most important that these labels shall be descriptive. Yet it is futile to expect every writer in every land to sacrifice the terms of his just choice to any Procrustean code, least of all to one with so little scientific, linguistic, or literary merit as the B.N.A. The B.N.A. is sublime in that at one stroke it disposed of 25,000 terms; it is ridiculous in that the 5000 which survive were mostly chosen individually by postal ballot.

The great objection against new terms, however good, is the difficulty of changing over. No doubt this is great if the terms are mere labels, but no new term should be adopted unless it is more descriptive than that which it is to displace or else falls more naturally into line with its fellows. The more simple and descriptive the international names, the more easily and naturally will they fit into national description either in their original or in a nationalised or even in a pure national form. Though the simplest name is not always the shortest, it will often be found that in the end the shortest description is that which uses the simplest names.

It cannot be too strongly emphasised that the writer is pleading not for a particular code, nor for particular names, but for the one guiding principle of simplicity based on the free use of the national tongue. In fixing the form of a nomenclature, national or international, it is well to begin with (though not perhaps at first to finish) the names for the body as a whole and for its parts, then to name all the bones, then all the joints and ligaments, and so on. It would be foolish for any one person to formulate a complete list of terms, because unless the foundations were laid in terms acceptable to the whole profession, or at least to all anatomists, the whole superstructure would be worthless.

In this paper, some of the outstanding principles will be stated and their application illustrated by a few examples. It will often be necessary to suggest names without even mentioning the corresponding British and B.N.A. terms. In some ways this will be an advantage as a test.

II.—The National Language.

The national language should be freely used. None but a crank would speak of a man's cerebrum as being within his caput, or of respiration being the function of his pulmones, or blood-circulation that of his cor. It is a pity that so few national words have hitherto been used with a precise anatomical meaning. One is never troubled by such words as leg, thigh, arm, neck, and for these one would seldom use the Latin crus, femur, brachium, cervix, although these are familiar through their adjectives crural, femoral, brachial, cervical. It only needs a wider use of home words such as groove, pit, pulley, coil, and many others, for these to become equally familiar in scientific thought. This does not mean that their Latin forms would never be used, but free choice would make description less wooden and more pliable, and the national forms would clarify the student's ideas, and if he knows no Latin and less Greek they would help him to master as much of these languages as is needed. At present he is overcome by the complexity of the human body and the mysterious language in which it is described, whereas if he were trained to think in simple English and easy Latin, he should not find it so hard to master and to remember the facts. Both English and Latin forms are needed, and everyone must be free to choose in every case. If some will insist on using only Latin, and others nothing but English, it will be difficult to get on, but if those who like Latin will temper it with English, and those who prefer English will season it with Latin, everyone may be happy. He is no friend of anatomy, medicine, or surgery, who in these days lays too much stress on his own likes and dislikes.

III.—The Direct Method.

Every name should be as direct as possible. This method has been explained by the writer in a paper in THE LANCET of Sept. 8th, 1917, and it will be enough here to give a few examples.

Direct.	Indirect.	Direct.	Indirect.
Stylus.	Processus styloideus.	Cricus.	Cartilago cricoidea.
Corax.	Processus coracoideus.	Thyreus.	Cartilago thyreoidea.
Corona.	Processus coronoideus.	Quadri-	Corpora quadri-
Sphen.	Os sphenoidale.	gemina.	gemina.
Ethmus.	Os ethmoidale.	Mammilla.	Corpora mammil-
Arytena.	Cartilago arytenoidea.	laria.	laria.

One advantage is the simplicity of the Latin name. Sometimes a simple national equivalent can be used—e.g., crow of the scapula. The adjectives, too, are convenient—e.g., styler, arytenal, ethmal, and compounds are readily found—e.g., thyreo-arytenal, stylo-hyal.

IV.—The Genitive and Adjective (Latin).

The genitive should be used for immediate and the adjective for more remote relation. This is well seen in the bones, e.g.:—

Corona ulnæ.	Incisura radii ulnaris.
Stylus radii.	Facetta claviculæ acromialis.
Incisura ulnæ radialis.	Facetta acromii clavia.

V.—The Use of the Diminutive (Latin).

Where there are two structures of a kind, one larger than the other, the latter may be distinguished by the diminutive.

Arm-bone—Tuber.	Tubercle.	Os brachii—Tuber.	Tuber-
			culum.
Sphen—Wing.	Winglet.	Sphen—Ala.	Alula.
Thigh-bone—Great trochanter.		Os femoris—Trochanter.	
Small trochanter.		Trochantellus.	

The single word provides a convenient adjective—e.g., alular. Thus one might say that the sphen had an alular (the optic) and three alar foramina (the round, the oval, and that of the angle, cf. arteria duræ angularis).

VI.—The Human Body. Corpus Humanum.

VII.—Parts of the Body.

For the main parts of the body, and for their chief subdivisions, national terms should be used, and only where these fail international, e.g.:—

- (i.) Head, neck, limbs, chest; face, nose, chin; liver, stomach, brain; shoulder, thumb, fingers, knee.
- (ii.) Abdomen, pelvis, perineum.

VIII.—Position and Direction.

(i.) The mid- or median plane.—Median should be reserved for the mid-plane—that is to say, the antero-posterior vertical plane which bisects the body. There is no median nerve.

(ii.) Anterior and posterior.—These can often be replaced by front- and back- (e.g., front-surface or back-surface, or, more simply, front and back of the arm); or, again, by fore- and hind- (e.g., fore-brain, hind-brain)—cf., above, below, upwards, downwards.

(iii.) *Superior and inferior.*—Interior and exterior express relative distance from the mid-plane. The slight catch here is easily mastered, since the termination is the same as in anterior and posterior, superior and inferior. Moreover, *inner* and *outer* can usually be employed.

(v.) *Internal and external.*—Internal and external express depth within an isolated structure—e.g., external and internal muscular layers of the bowel. Inner and outer can often be used without risk of confusion.

(vi.) *Superficial and deep.*—Superficial and deep should be retained for depth within the body—e.g., the superficial and deep lymph-glands of the groin. At the same time, internal and external and superficial and deep may often be interchanged without confusion.

(vii.) *Lateral.*—Lateral should express symmetrical relation to the body (head, neck, and trunk only). E.g.—Lateral walls of the abdomen, lateral branches of the thoracic nerves. A good example of the use of these and other terms is found in the groin.

IX.—The Groin in Relation to Hernia.

(i.) *Hernia of the abdomen.*—These are umbilical, inguinal (upper and lower), diaphragmatic, and so on.

(ii.) *The groin.*—The groin is the region where abdomen and thigh meet in front, along the line of the limiting tendon, which consists of two parts, the interspinous, swinging between the spines of the iliac and pubic bones, and the lacunar (or gap-tendon), filling in the inner part of the interval bridged by the interspinous tendon.

(iii.) *Canals of the groin.*—These are a lower and an upper.

(iv.) *Lower canal of the groin.*—This leads into the thigh and has a fascial ring and a fatty septum.

(v.) *Upper muscles of the groin.*—These are the superficial, middle, and deep muscles of the lateral wall of the abdomen. Each has a superficial and a deep fascia (in the B.N.A. sense), but the two most important of these are the superficial fascia of the superficial and the deep of the deep muscle.

(a) The *superficial muscle* in the groin is inserted into and actually forms the limiting tendon in its whole length, gaining attachment to the iliac and pubic bones through the interspinous and to the pectineal crest through the lacunar portion. It has also a decussate tendon which crosses to the other side.

(b) The *middle muscle* in the groin arises from the outer half of the interspinous tendon, and is inserted into the pubic and pectineal crests, mostly in conjunction with the corresponding tendon of the deep muscle, thus forming the conjoined tendon.

(c) The *deep muscle* in the groin arises from the outer third of the interspinous tendon, and is inserted by means of the conjoined tendon.

(vi.) *Upper canal of the groin.*—This pierces the three lateral muscles of the abdomen and their fasciae, and it has three rings, deep, middle, and superficial, from each of which there passes into the scrotum a fascial (or fascio-muscular) sac, the deep sac being derived from the deep fascia, the middle sac from the deep and middle muscles (conjoined tendon), and the superficial sac from the superficial muscle and its superficial fascia.

(vii.) *The peritoneum* in the groin lines the abdominal wall, and has three pits or fossae, inner, middle, and outer (interior, media, exterior), at the last of which it is evaginated through the upper canal of the groin into the scrotum. The upper part of this evagination becomes obliterated, but the lower persists as a sacculi in relation with the testis and its cord.

(viii.) *Descent of the testis.*—The testis leaves the abdomen through the outer pit, descending into the scrotum by way of the upper canal of the groin, at each ring of which it receives a covering. It is therefore covered in by:—

- i. Skin. Subcutaneous tissue.
- ii. Superficial, middle, deep sacs.

(ix.) *Hernia of the groin.*—These are lower or upper, according as they pass below or above the limiting tendon.

Lower hernia pass into the thigh (being usually called femoral). *Upper hernia* make their way towards the scrotum (being often called scrotal), and are outer, middle, or inner, according as they begin opposite the outer, middle, or inner pit of the peritoneum.

An *outer hernia* starts at the outer pit, and, covered by peritoneum and extraperitoneal tissue, it passes through the deep, middle, and superficial rings of the upper canal, appropriating in turn the three sacs which enclose the testis and its cord, and which are themselves covered in by the subcutaneous tissue and skin.

A *middle hernia* starts at the middle pit, and, covered by peritoneum and extraperitoneal tissue, it bursts through and makes a special covering for itself out of the deep fascia, and then it passes through the middle and superficial rings, appropriating the middle and superficial sacs, which are themselves covered in by the subcutaneous tissue and skin.

An *inner hernia* starts at the inner pit, and, covered by peritoneum and extraperitoneal tissue, it bursts first through the deep fascia and then through the conjoined tendon of the deep and middle muscles, and perhaps also the decussate tendon of the opposite superficial muscle, and, having thus made for itself two special coverings, it passes through the superficial ring, appropriating the superficial sac, which is itself covered in by the subcutaneous tissue and skin.

Outer, middle, and inner hernia might also be called direct, and outer and inner indirect, according to their relation to the upper canal of the groin.

X.—On Proper Names.

Proper names should be avoided in writing, although each school may teach the names of those who have done good service to anatomy there or elsewhere.

In the past proper names were recklessly used. Thus, the ileo-caecal valve was also known as the valve of Bauhinus, the valve of Tulpius, and the valve of Fallopius. Again, although the limiting tendon of the groin was unnamed, its interspinous and lacunar portions were known as Poupart's and Gimbernat's ligaments. The student's chief interest in Poupart is usually whether the name should be pronounced Poopah or Powpart, and he always has an uneasy feeling that something is wrong with Gimbernat, who may after all have been a Frenchman. Again, the mid-brain canal is

called the aqueduct of Sylvius. Now, "Who is Sylvia?" is an interesting enough question, but why worry about Sylvius? The writer once heard Sir William Turner explain to his class that Sylvius was an Englishman named Wood, and that fissura Sylvii was adopted for Wood's fissure because it sounded and looked so much better than fissura Woodi. Perhaps, however, Sir William was only making merry. Be that as it may, an anatomical lecturer much more learned in such things than the writer recently claimed that Sylvius was one or other of two Frenchmen (he did not know which), whose names were Le Bois and Du Bois, or the like. Lastly, a physician was recently pleading for keeping this name "out of reverence for the master who taught in Florence." "Padua," said the writer at a venture. "Padua, to be sure," replied the physician unabashed.

And so the smoking torch of knowledge is handed on, each receiving it reverently, and reverently passing it on without troubling to see whether within the smoke there is or ever has been any light.

XI.—The Bones.

Every bone should be named after the region or part of the body to which it belongs, and where such region or part contains more than one bone these should be distinguished by some feature, actual or fanciful. It is more important that names derived from such features should be short and simple than that they should be specially appropriate.

Thigh—Thigh-bone.	Femur—Os femoris.
Arm—Arm-bone.	Brachium—Os brachii.
Leg—Leg-bone.	Crus—Ossa cruris: Tibia, fibula.
Wrist—Wrist-bones: Skiff-bone, moon-bone, wedge-bone, pea-bone, saddle-bone, boot-bone, great bone (of the wrist), hook-bone.	Carpus—Ossa carpi: Scaphus, luna, cuneus, pisum, sella, cothurnus, magnum, uncus.
Brow—Brow-bone.	Frons—Os frontis.
Temple—Temple-bone.	Tempus—Os temporis.
Nose—Nose-bone.	Nasus—Os nasi.
Cheek—Cheek-bone.	Mala—Os malæ.
Palate—Palate-bone.	Palatum—Os palati.
Flank—Flank-bone.	Ilium—Os ilii.
Lower limb—Girdle-bone: Flank-bone, bone of the pubes, sciatic bone.	Membrum inferius—Os cinguli: Os ilii, os pubis, os sciaticum.

Notes.—(1) Humerus is not needed for the arm-bone and badly needed for the shoulder, which has at present no international name. The B.N.A. articulation humeri begs the question. (2) Those who stickle for linguistic accuracy and object to os temporis, os ilii, should bear in mind that ilium is a genitive plural, pubis a genitive singular, and ischium the name of a region. Nomenclature should be the handmaid and not the mistress of science.

XII.—Parts of the Bones.

(i.) The parts of a bone should be named intrinsically, each part having a name indicating its character (actual or fanciful) and its relation to the bone itself without reference to any other part of the body.

Radius—Style.	Radius—Stylus.
Ulna—Crown.	Ulna—Corona.
Scapula—Crown.	Scapula—Corax.

(ii.) Where this is not satisfactory an extrinsic term may be employed, the part of the bone being distinguished by its relation to some structure or part of the body other than the bone itself.

(a) A trial may be made with a local term, the part of the bone being named after its relation to some neighbouring structure or part.

Thigh-bone—Patellar surface.	Os femoris—Facies patellaris.
Ulna—Radial notch.	Ulna—Incisura radialis.
Scapula—Vertebral border.	Scapula—Margo vertebralis.

(b) A general term may have to be tried, the part of the bone being named according to its position in the body.

Limbs—Upper, lower.	Membra—Superius, inferius.
Scapula—Angles: Upper, lower.	Scapula—Anguli: Superior, inferior.

(c) It may be necessary to appeal to comparative anatomy for a term, especially in relation to development. All such terms should be avoided as much as possible. It is almost beyond belief that anyone should wish to change upper and lower for cephalic and caudal. "We're not as tabbies are," and there is no reason why human anatomy should continue on its belly with its tail sticking out behind it, when the being whom it is supposed to describe has long since got his back up, defied his tail, and walked upright.

(d) If all the above fail, some adventitious name may be chosen, perhaps to the glory of some investigator. Proper names should, however, only be adopted if no others can be found satisfactory.

The intrinsic and extrinsic methods should preferably be employed in the order given above and they may be applied to the scapula. This is a flat triangular bone with two surfaces, three angles, and three sides or borders. It is natural therefore to look for an apex and a base, and these are best found in the outer angle and the posterior or vertebral border, and the two other angles thus become the basal angles. Since the intrinsic method will yield no more the remaining sides may be distinguished by local extrinsic terms as the cervical and axillary borders, and similarly these are costal and dorsal surfaces, dorsal being here used with a local rather than a general significance. The remaining angles would be distinguished by more general epithets as the upper and lower basal.

This method, which is by no means essential, might avoid considerable discussion and the international terms, though labels,

would be descriptive. But these terms would not need to be slavishly followed, and it would be open to anyone to speak of the vertebral border, or the outer angle, or the deep surface, provided always that the context was so plain that no confusion could arise. Wherever there was any risk the international terms should be used in either the Latin or an Anglicised form. As national equivalents the writer prefers for general use superficial and deep surface, outer, and upper and lower (basal) angles, and posterior, upper and outer borders, as well as the alternatives apex and base. The last is very convenient in dealing with the muscles. Also, super- and sub- have their place—e.g., suprascapular muscles.

The arm-bone has many parts which can be named intrinsically, although extrinsic epithets can always be added. There are times when the student may like to pick up a bone and study it by itself, without for the moment troubling about its relations to any structure except the other parts of the skeleton. Thus one might take a rapid survey of the head, anatomical neck, tuber and tubercle with the straight groove (with its floor and inner and outer crests), surgical neck, shaft, spiral groove, eminence, line, outer and inner borders, anterior surface (with inner and outer areas), posterior surface, radial and ulnar (both coronal and olecranal) pits, little head, pulley, and inner and outer nodes (the former with its groove).

A word about condyle. It is curious that the metacarples should in these days have heads instead of condyles, although their heads form the condyles (κόνδυλοι) or knuckles from which the term is derived. What in these days is a condyle? And what an epicondyle? While the metacarples have neither condyles nor epicondyles, the tibia and occipital bone have condyles but no epicondyles, the arm-bone has epicondyles but no condyles, and the femur has both condyles and epicondyles. A condyle may be a more or less definite knuckle with a convex facet as in the femur, or, again, an ill-defined mass with the concave facet into which that knuckle fits as in the tibia. Why not, then, use condyle for any knuckle of bone with a facet? The condyle of the mandible is described as including the neck as well as the head with its facet. Why not let the arm-bone have its upper condyle or knuckle with the head, anatomical neck, tuber and tubercle, and its lower condyle or knuckle with the little head, pulley, and inner and outer nodes? The epicondyles would then vanish into the limbo whence they came. The lower condyle of the femur would in this way consist of inner and outer condyles with the intercondylar notch.

XIII.—The Joints and Ligaments.

A. The Joints.

Every joint should be named after the bones which it articulates, and should be regarded as provided by one bone which is fixed for the benefit of another which is movable.

The movable bones may be regarded as articulated in succession. The nucleus of the system is the sacrum, which provides for the movement of (i.) the coccyx, (ii.) each vertebra in succession up to the axis, which in turn provides for the atlas, and this again for the skull, on which finally the lower jaw moves. The vertebrae provide for the ribs, and these again for the sternum. For the upper limb the clavicle is articulated with the sternum, the scapula with the clavicle, the arm-bone with the scapula, the bones of the forearm with the arm-bone, the radius also with the ulna, the first row of wrist-bones with the bones of the forearm (though separated from the ulna by the triangular septal cartilage), and so on. In the wrist the individual bones are articulated in succession from without inwards—e.g., the scaphus takes on the lunate, the lunate takes on the cuneus, and the cuneus takes on the pisum, and so with the second row. So also throughout the lower limb.

The practical result of the succession of the bones is that in the international list most of the joints can be named after the bones which form them. In national description the joint of the clavicle with the sternum may, according to the context and the preference of the individual writer, be named in any of four ways—namely, sternoclavian joint, clavisternal joint, sternal joint of the clavicle, clavian joint of the sternum. For the international list one only of these forms can be admitted and here the rule of succession comes into play, so that this joint would be either the sternoclavian joint or the sternal joint of the clavicle. Although in its full form the latter is the longer, it is to be preferred, because in practice it is really simpler and can often without confusion be reduced to the sternal joint of the clavicle or even the clavicular joint. Thus, in describing the sternum one may speak of its clavicular and costal joints, whereas in describing the clavicle one may equally well speak of its sternal and scapular (or acromial) joints. Moreover, one can use this form for making the name more detailed and precise as the sternocostal joint of the clavicle.

The rule of succession would be of value chiefly in determining the form of the international terms. The scapular joint of the arm-bone would, of course, usually be spoken of in Britain as the shoulder-joint. On the other hand, the elbow-joint is so complex that it would appear as such in the international list also.

On this principle one might enumerate those joints of the upper limb which have a complete capsule as follows:—

Sternocostal joint of the clavicle.	A. claviculæ sternalis.
Clavicular joint of the scapula.	A. scapulæ claviculæ.
Scapular joint of the arm-bone.	A. (ossis) brachii scapularis.
Elbow-joint.	A. cubiti.
Wrist-joint.	A. carpi.
Cuneal joint of the pisum.	A. pisi cunealis.
Complex joint of the table of the hand.	A. manus tabulæ complex.
Sellar joint of the thumb metacarpale.	A. pollicis metacarpuli sellaris.
Interphalangeal joints.	Aa. interphalangeales.

Once the rule of succession had become familiar the international terms could be reduced to A. claviculæ, A. scapulæ, A. brachii, A. cubiti, A. carpi, A. pisi, A. manus complex, A. pollicis metacarpuli, A. phalangis secundæ, A. phalangis tertie. The various British equivalents which might be substituted for the above are too obvious to be given here.

The same method may be applied to the part-joints—e.g., the elbow-joint may be tabulated as follows:—

Elbow-joint.

- (i.) Brachial joint of the forearm. Brachial joint of the ulna. Brachial joint of the radius.
- (ii.) Upper joint of pronation. (Brachial joint of the radius.) Upper ulnar joint of the radius.

The wrist-joint to be in harmony with the other septate joints should include the lower joint of pronation and the radio-septal joint of the wrist.

Other examples of succession in their short form are A. pisi, A. cubi, A. mandibulæ, A. phalangis primæ pollicis.

B. Classification of the Joints.

Whatever nomenclaturists devised the names for the various types of joints must have wallowed in Greek—of a kind. Symphysis, arthrodis, ginglymus, gomphosis, synchondrosis, synarthrosis, enarthrosis, diarthrosis, amphiarthrosis, syndes—Moses! What a list for a student who knows no Latin and less Greek.

(i.) *Movable and immovable joints.*—Each joint may be regarded as provided by a bone which is fixed for another which may or may not be movable, the ligaments and muscles being regarded as arising from the former bone for retaining or moving the latter.

(ii.) *Continuous, partly continuous, and discontinuous joints.*—The continuous are immobile, whereas the partly continuous and discontinuous are mobile.

(iii.) *Continuous joints.*—These may be distinguished by the character of the uniting tissue, as membranous, cartilaginous, and ossified, and the membranous, which may retain the name of sutures, may be distinguished according to the form of the articulating surfaces—e.g., linear, plane, serrate, sulcal, alveolar, squamous.

(iv.) *Partly continuous joints.*—Such are the intercentral joints of the vertebrae. Singly these present little movement, but from the point of terminology we may glance at the movements which might take place between any two discs separated by a firm but elastic medium.

(a) *Rotation.*—The moving disc may rotate on the fixed disc around its own axis which may be regarded as perpendicular.

(b) *Lapse.*—The moving disc may slip bodily on the fixed disc, in which case its axis remains perpendicular but is shifted out of place.

(c) *Flexion.*—The moving disc may be tilted, in which case its axis leans over to one or other side.

(d) *Approximation and separation.*—The moving disc may approach or go away from the fixed disc.

(e) *Mixed movements.*—Thus, theoretically, all these movements might take place at once.

(v.) *Discontinuous joints* are either (a) ligamentous (e.g., lower tibial or fibular), or (b) capsular, the former giving slight lapse only, the latter giving varying degrees of rotation, lapse, and flexion, but of course, no approximation or separation.

Capsular joints may best be distinguished according to the nature of the facet provided by the fixed bone—e.g., plane, concave, convex, and so on.

(a) *Plane joints*—e.g., cuneal of the pisum.

(b) *Concave joints.*—Uniconcave or notch-joints (incisural)—e.g., upper ulnar of radius. Biconcave or boat-joints (navicular)—e.g., radio-septal of wrist. Universal concave or cup-joints (pocular). These are shallow cup- or glenoid as at the shoulder, and deep cup- or cotylar as at the hip.

(c) *Convex joints.*—Uniconvex or wheel-joints (rotal)—e.g., lower ulnar of radius. Biconvex joints (antinaricular?)—e.g., astragalar of scaphus, which is almost a ball-joint. Universal convex or ball-joints (global)—e.g., brachial of radius.

Or the facet may be a modification or combination of the above, e.g.:—

Irregular joints—e.g., between some of the wrist-bones.

Concavo-convex joints—e.g., joint of the second row of carples.

Saddle-joints (sellar)—e.g., joint of the thumb metacarpale.

Pulley-joints (trochlear)—e.g., brachial of the ulna.

Antitrochlear joints—e.g., part of the ankle-joint.

Capsular joints may also be classified according to the nature of the movements which actually take place in the moving bone, e.g.:—

Labile—e.g., femoral of patella.

Flexile.—Uniflexile or hinge (cardinal)—e.g., elbow. Biflexile—e.g., radio-septal of wrist. Universal flexile—e.g., shoulder, hip.

Capsular joints may also be: *Septate*, having a septal cartilage—e.g., temporal of mandible. *Compound*, being formed by more than two bones—e.g., knee, elbow, astragalar of heel-bone and scaphus.

In compound joints one may need to study: (a) the form of each facet, simple and compound. (b) The movements which each facet should allow. (c) The limitations imposed by ligaments and neighbouring structures. (d) The movements which actually take place at each facet. (e) The movements which actually result in the part—e.g., thigh, hand.

Capsular joints show only rotation, lapse, or flexion, or combinations of these, and flexion may be further defined according to the direction—e.g., forward, backward, inward, outward, upward, downward, or by the special terms flexion, extension, adduction, abduction, levation, and depression.

C. The Ligaments.

The ligaments of the capsular joints are: (i.) the capsule, parts of which may form capsular ligaments; (ii.) accessory ligaments.

(i.) Capsular ligaments may be briefly named after the joint—e.g., anterior, posterior, inner, and outer of elbow-joint, or more strictly of the brachial joint of the forearm. Sometimes a bony relation will be mentioned—e.g., upper, middle, and lower glenoid of the shoulder-joint, or iliac, pubic, or sciatic of the hip-joint, or, again, the collar ligaments of the radius and thigh-bone.

(ii.) Accessory ligaments will mostly be named after bony attachments—e.g., costal of the clavicle, clavian of the crow, fibular of the tarsus (or outer of the ankle), the last consisting of the anterior and posterior fibular of the astragalus and the fibular of the heel-bone.

Ligaments which join two parts of the same bone may be named in two ways—e.g., (1) coraco-acromial, (2) ligament of the notch of the hip-cup or acetabulum, according as the two parts have special names or not.

XIV.—Muscles.

Every muscle should be named after its origin and insertion, and where necessary or convenient the name should indicate not merely the bones concerned but the actual parts to which the muscles are attached.

Had we been living in the days when Latin was the language of science this problem would have presented little difficulty. An eminent anatomist has recently pleaded for a nomenclature based on an exhaustive study of many different languages. Such a hope is futile. It is difficult to find five men interested in their own national terminology, and how shall we find even one interested in ten? Fortunately, the names are to be found by the study not of many national nomenclatures but of the body itself. In the case of the muscles, the aim should be either brevity with all possible description or description with all possible brevity. The writer prefers the latter.

One of the best examples for illustrating the method is the latissimus dorsi (Br., B.N.A.) because of its complex origin and well-defined insertion. The insertion would be arrived at by what might be called the step-method.

			Arm.
		Bone of Arm.	
		Straight groove of Bone of Arm.	
	Floor of	Straight groove of Bone of Arm.	
	Muscle of Floor of	Straight groove of Bone of Arm.	
	Nerve of Muscle of Floor of	Straight groove of Bone of Arm.	
		Brachium.	
		Os	Brachii.
		Ossis	Brachii.
	Fundus	Sulci recti	Ossis
	Musculus Fundi	Sulci recti	Ossis
	Nervus Musculi Fundi	Sulci recti	Ossis

To the genitive of the insertion would be added the adjective of the origin. This muscle would therefore become the iliopspinal, costal and scapular muscle of the floor of the straight groove of the arm-bone, M. iliopspinalis et costalis et scapularis fundi sulci recti ossis brachii, and it might well adopt for its motto, "Nemo me impune lacessit." After all, however, the costal and scapular origins are subordinate, and since the student is not likely to be misled into wondering whether the muscle acts upon the fundus of the stomach or bladder or even on that of the eye, it will be enough to speak of the iliopspinal of the floor, iliopspinalis fundi, and on occasion the name may be even further shortened, so that, e.g., the muscles of the posterior wall of the axilla might be enumerated as the subscapular, the iliopspinal and the angular (subscapularis tuberculi, iliopspinalis fundi, angularis cristæ interioris). We should also have the nerve to the iliopspinalis fundi.

Other Examples.

(1) The muscles inserted into the mastoid (?) are the sterno-clavian, the spinal, and the alo-articular. (N.B. Ala = processus transversus.)

(2) The scalene (?) group consist of the anterior and posterior scalenes of the first rib and the scalene of the second rib.

(3) The muscles attached to both bones of the shoulder girdle are the occipitospinalis of the girdle and the circularis of the arm.

(4) The pectoral muscles are the pectoral of the clavicle, pectoral of the scapula, and pectoral of the arm, or in greater detail, the pectoral or costal of the groove of the clavicle, pectoral or costal of the crow of the scapula, pectoral or sterno-costo-clavian of the outer crest of the straight groove of the arm-bone.

(5) The muscles inserted into the scapula only are the alar, the upper and lower spinal, the costal of the base, and the pectoral or costal of the crow.

(6) The deltoid and coraco-brachialis (e.g.) and their bony attachments become the circularis of the eminence and the eminence of the circularis, the coracalis of the line and the line of the coracalis.

(7) In the outer column of the erector of the back the three muscles become the iliac of the angles, the interangular, and the angular of the ala (ala = processus transversus, chiefly because short and simple).

(8) The muscles inserted into the arm-bone are the supraspinatus, infraspinatus, and marginal of the tuber, the subscapular of the tubercle, the iliopspinal of the floor of the straight groove, the angular of its inner and the pectoral of its outer crest, the circular of the eminence, and the coracalis of the line.

(9) The muscles of the lateral wall of the abdomen are the superficial, middle, and deep (here the bony attachments are too complex).

(10) Arising from the style of the temple-bone are the styler muscles of the tongue, of the pharynx, and of the U-bone (or hyal bone).

(11) The extrinsic muscles of the tongue are the styler, the hyal, and the palatine of the tongue and the submental of the tongue and U-bone.

(12) The muscles of the mouth are i., the annular or ring-muscle and the buccinator or trumpeter; ii., (a) the mandibular of the lower lip; (b) the mandibular, risorius, malar, and canine of the angle; (c) the malar, infraorbital, and angular of the upper lip, with which last is associated the angular of the ala of the nose.

(13) The constrictors of the pharynx are the upper or pterygo-mandibular, the middle or hyal, and the lower or thyreo-cric.

(14) Iliocentral of the trochantellus.

Iliac of the trochantellus.

Central of the trochantellus.

Superthyrat of the pit of the trochanter.

Subthyrat of the summit of the trochanter.

Calcaneal extensor.

Biceps of the tubercle of the radius.

Triceps of the heel.

Biceps pronator.

Prænodo- { heads.

Coronal {

Prænodo- of the index metacarpale.

Prænodo- of the palmar fascia.

Prænodo-ulnar of the pisum.

Triceps of the second phalanges.

Radial of the third phalanges.

Tibial flexor of the toes.

Fibular flexor of the great toe.

Sphenopterygal of the neck of the mandible.

Pterygo-maxillary of the angle of the mandible.

Tubosphenal tensor of the palate.

Tubopetrous levator of the palate.

Everything depends on how the international terms are to be used. If national description is slavishly to employ only the international terms it will remain for ever wooden, dry, and dead; but if it be allowed the simplicity and fluency of the national tongue it will live during the period of study and survive in the memory. Most of the muscles are sufficiently defined by short names, the word muscle being avoided by the Latin form—e.g., occipitospinalis, circularis, alaris scapulae, extensor calcaneus, tubosphenalis, subthyrat, gemellus spinosus, musculus pisi, brachialis coracis, coracalis, flexor secundarum. The thyrat muscles are the subthyrat culminis trochantri and the superthyrat fossæ trochantri, but these are sufficiently defined as the subthyrat culminis and the superthyrat fossæ, or even as the sub- and super-thyrat. They may be grouped together as the thyrates.

In many cases classification will do away with undue formality—e.g., the prænodo-ulis indicis metacarpuli, prænodo-ulis palmar fasciæ, and prænodo-ulis pisi—may well be classed in national description as the outer, middle, and inner flexors of the wrist. So, too, the pectorals may be distinguished as the great, the middle, and the small—cf., glutei.

XV.—Nerves.

Everything being so contingent it is not proposed to deal here in great detail with the nerves.

(i.) A nerve shall retain or suggest its name from beginning to end.

The trigeminus splits into three parts—the first, frontal or supra-orbital geminus; the second, maxillary or infraorbital geminus; and the third, mandibular or mental geminus.

Trigeminus.

First geminus.

Branches: Lacrimal.

Nasal.

Supratrochlear.

Second geminus.

Third geminus.

N. trigeminus.

N. geminus primus.

Rami: Lacrimalis.

Nasalis.

Supertrochlearis.

N. geminus secundus.

N. geminus tertius.

(ii.) A motor nerve shall be named after the muscle or muscles which it supplies, and if that is not satisfactory after a bone or other structure with which it comes into relation.

One would thus have the nerve to the circularis, nerves to the alaris of the scapula, nerve to the spinales of the scapula, nerve to the spinati, nerve to the coracalis, nerve to the costalis of the base of the scapula, nerve to the clavicular pectoral, nerves to the temporalis, nerves to the pterygo-maxillaris, nerve to the styleris of the pharynx, nerve to the thyrat cric.

(iii.) A mixed nerve shall be regarded as a motor nerve giving off sensory branches.

Thus the ulnar nerve has muscular branches and ends in muscles, and it also gives off cutaneous branches—namely, one to the back of the hand, one to the palm of the table of the hand, and several to the palm of the fingers, or, in other words, a dorsal manual, a palmar tabular, and several palmar digital cutaneous branches; or, again in other words, the ulnar dorsal manual, ulnar palmar tabular, and ulnar palmar digital cutaneous nerves.

Again, the spiral nerve (Br., musculo-spiral; B.N.A., radial) ends on the back of the hand, giving off cutaneous branches—namely, two to the arm, one to the forearm, and one to the hand; or, in other words, two brachial, an antibrachial, and a manual cutaneous branch; or, again in other words, the spiral cutaneous nerves of the arm, forearm, and hand.

From this point of view it is well to make the nerves as long as possible—e.g., to carry back the ulnar nerve right up to the spinal cord, in which case it would arise by two roots, and then proceed successively through the neck, axilla, arm, forearm, and hand, giving off, among others, a pectoral muscular branch, and brachial and antibrachial cutaneous branches; or, in other words, the ulnar pectoral nerve, and the ulnar cutaneous nerves of the arm and forearm. This can be done with the other great nerves derived from the brachial plexus.

The international terms may be chosen by a method which will be illustrated in the case of the arteries. Some will be named as branches of the parent trunk, others as nerves supplying certain structures.

XVI.—Arteries.

The principles governing the naming of the arteries somewhat resemble those for the nerves. Thus the arteries should be given names which will extend over as long a stretch as possible—e.g., the left brachial artery begins at the aorta and is distributed to the whole limb. At the same time its main divisions and branches may for convenience be called by separate names.

The heart gives off the systemic artery (= aorta) and the pulmonary artery.

The aorta gives off the arteries of the heart (= Aa. cordis), the cervico-brachial and the left cervical and left brachial arteries. The left brachial has a thoracic, a subclavian, an axillary and a brachial (proper) part (e.g., = subclavian artery, axillary artery), and it then divides into radial and ulnar parts (= radial and ulnar arteries), which again divide into superficial and deep vessels, which finally stomatose to form the corresponding arches of the palm.

The left cervical artery ascends through the thorax and neck and divides into the temporo-facial and the petrous artery of the brain (cf. vertebral artery of the brain).

The temporo-facial divides into a temporal, and two facial parts (= A. temporis, A. faciei superficialis, and A. faciei profunda), and it has certain other branches—namely, thyreal (= A. glandulae thyrealis superior), lingual (= A. linguae), post-auricular (= A. post-auricularis), and occipital (= A. occipitis).

The petrous artery of the brain divides into cerebral branches (= A. cerebri anterior, A. cerebri media).

The cervico-brachial (= A. cervicis et brachii, which is more convenient than A. capitis et membri superioris) divides into the right cervical and right brachial, which resemble the left except that they have no thoracic part.

And so on.

The method is well seen in the axillary artery, the branches of which go (a) to the inner, (b) to the anterior, (c) to the posterior, and (d) to the outer wall of the axilla.

Cervico-brachial artery = A. cervicis et brachii.

Brachial artery = A. brachii.

Axillary part = Axillary artery = A. axillae.

Thoracic branch = Axillary thoracic artery = A. thoracis axillaris.

Pectoral branches

= Pectoral arteries

= Aa. pectoris.

Upper.

Superior.

Lower.

Inferior.

Scapular branch = Outer scapular artery = A. scapularis exterior.

Brachial branches

= Brachial circumflex arteries = Aa. brachii circumflexae.

Anterior.

Anterior.

Posterior.

Posterior.

The systemic artery or aorta divides into the pelvi-femoral arteries, each of which again divides into the pelvic and femoral arteries, the latter having an iliac portion (= iliac artery = A. ilii), an anterior femoral portion (= A. femoris anterior) and a popliteal portion (= A. poplitae), which last divides into the anterior and posterior arteries of the leg (Aa. cruris anterior, posterior), which latter gives off the fibular artery (= A. cruris fibularis), and ultimately divides into the inner and outer arteries of the sole (= Aa. plantae interior, exterior).

Enough.

Whatever system is adopted, there must be plenty give and take, and probably for everyone more giving than taking.

XVII.—Correlation.

Some examples of correlation may be given.

(i.) Pectoral region.—Pectoral fascia; Pectoral membrane

Pectoral muscles—Of the arm = great pectoral. Of the scapulae = middle pectoral. Of the clavicle = small pectoral.

Pectoral nerves: Radial pectoral—Upper = Nerve to the small pectoral. Lower = Nerve to the great and middle pectorals.

Ulnar pectoral = Nerve to the middle pectoral.

Pectoral arteries: Upper; Lower.

Pectoral cutaneous branches of the cervical nerves: Inner; Outer. (Cf. also humeral cutaneous branches.)

(ii.) Thyra (i.e., door) of the pelvis.—Thyral groove. Thyral tubercles. Thyral membrane. Thyral muscles; Superthyral. Subthyral. Thyral nerve. Thyral artery.

(iii.) Occipital bone.—Jugular foramen. Jugular sinus. Jugular vein. Jugular nerve of the pharynx. Wandering jugular nerve. Jugular nerve of the girdle.

(iv.) Scapular stomatosis.—The scapular arteries—posterior, upper, and outer—stomatose freely in the subscapular fossa, at the base and beside the upper and lower basal angles, and in the suprascapular fossa (supra- and infra-spinat). The posterior is found in all these places, the upper fails only at the lower angle, while the outer fails above the spine—that is to say, in the supraspinat fossa and at the upper angle.

(v.) The heart.—Trabecular, pectinate, moderator, papillary muscles.

(vi.) Branches of the aorta to the alimentary canal in abdomen.—First, second, third enteric arteries.

(vii.) The primitive enteron becomes moored to the posterior abdominal wall by the common mesentery and each of the organs into which the tube becomes differentiated has a corresponding part of the common as its own special mesentery—e.g., gastric, duodenal, jejuno-ileal, and colic mesenteries. The splenic portion of the gastric mesentery at one time consists of the parietal ligament of the spleen and the splenic ligament of the stomach. Later it is represented by the renal ligament of the stomach, which consists of the renal ligament of the spleen and the splenic ligament of the stomach. So, too, the pancreatic portion of the gastric mesentery at one time consists of the parietal ligament of the pancreas and the pancreatic ligament of the stomach. Later the pancreas loses most of its parietal ligament and becomes fixed to the wall, and the pancreatic ligament of the stomach is divided by the transverse colon into the pancreatic ligament of the colon (also called the secondary mesentery of the transverse colon) and the colic ligament of the stomach (also called the omentum).

(viii.) The liver and duodenum descending into the abdomen draw down the umbilical and portal veins and so give rise to the umbilical and portal ligaments. The liver has also its phrenic ligament, consisting of three parts, right, left, and coronary.

(ix.) The Mullerian ducts ultimately form the uterus and its tubes. On each side there is a common mesentery of the uterus and tube, which is regarded as being divided by the attachment of

the ovarian mesentery into a mesentery of the uterus and a mesentery of the tube. The common and ovarian mesenteries together form the broad ligament of the uterus.

(x.) The urinary bladder has two lateral and one posterior reflection of peritoneum, and three peritoneal ligaments, one urachal and two ureteric.

(xi.) The testis has a fibrous tunic, a fibrous hilus, and fibrous septa. Its duct forms the epitestis, and its artery, veins, lymph-vessels, and nerves form its cord (e.g., tunica fibrosa, hilus fibrosus, arteria testis, plexus venarum testis, suspensor testis, nervus suspensoris testis, chorda testis).

(xii.) The brain (cerebrum) is developed from three ventricles, each being a bellying out of the neural tube and consisting of a wall and a cavity. The cavity of the second or mid-brain ventricle becomes the mid-brain canal, and that of the third or hind-brain ventricle becomes the hind-brain cavity and hind-brain canal. The first or fore-brain ventricle becomes the thalamus or chamber of the brain (with roof, floor, and four walls), the sides of which have bellied out and become moulded to form the lateral ventricles, the surface of which is marked by coils with intervening fissures and grooves, while the cavity consists of a body with frontal, temporal, and occipital recesses, and has a mouth through which it joins the thalamic cavity.

The brain is intricate enough without hypnotising the student by polysyllabic profundity. Encephalon, rhombencephalon, telencephalon, myelencephalon, prosencephalon, metencephalon, dien-cephalon, and the rest! "Sack the lot!" No one will suffer apart from the scoliotic lovers of turgid and turbid sonorosity. It is not as though all the above terms were used in the same sense by everyone, for it is worthy of note that those who indulge too freely in such terms are apt to become so intoxicated by the exuberance of their own terminological eloquence that they cannot agree among themselves.

Very little has been said of the organs, but of the making of terms there is no end, and many examples are a weariness of the flesh.

XVIII.—Afterword.

Cui bono? Who benefits?

The writer? This was answered by John Barclay in his New Nomenclature at the beginning of last century.

The student? The writer has given up most of his leisure for some 15 years in the belief that if anatomical terminology were set on a proper basis it would greatly "facilitate the progress of study" by removing much of the "rubbish that obstructs the journey." A sound knowledge of anatomy oils the wheels of the medical curricula. Besides, why make the student a terminological inexactitudinarian?

The teacher? The more "rubbish" removed and the less wearisome the labour of the student the easier will be the task of the teacher.

The patient? The sounder the anatomical knowledge of the graduate the better for the patient. The student need not devote his whole course to anatomy, nor need he be kept from graduating until he can enumerate the branchlets of every artery in order and at breakneck speed. He should, however, be given a sporting chance of acquiring in the time at his disposal a serviceable and lasting knowledge of the human body.

There is probably no change suggested above against which objections could not be brought. It is always so much easier to pull down than to build. At one time it is hard to find a suitable term, at another hard to choose the best of several, and so on. Moreover, everything is contingent. One can only make suggestions. The writer has studied the problems involved in the naming of almost every structure in the body, and he believes that if only a definite nucleus were provided the whole terminology would crystallise out. In these strenuous days one cannot devote a lifetime to the complete solution and exposition of a problem the practical issue of which depends entirely on others; but if the authorities responsible for anatomy and for medicine and surgery in general should think the time opportune for revision, the writer, were he able in any way to help, would feel more than repaid for the loss of the leisure of years. Anatomy is among the most precise of sciences. Why should she not lead the way in the science of terminology?

HOSPITAL FUNDS IN BELFAST.—It is announced that a sum of £6000 has been allocated to Belfast by the management of the United Services Fund, of which £1500 is to be given to the Royal Victoria Hospital, £1200 to the Mater Infirmorum Hospital, the balance to be divided among the Children's and other hospitals in Belfast, after deducting £750 to be devoted to the funds of the "Comrades of the Great War" Club. This announcement was made on August 20th at a meeting of the committee in charge of the Hospital Gala Sports Fund, the object of which is to raise £10,000 for hospital institutions in Belfast.

PUBLIC HEALTH IN SOVIET RUSSIA.

By L. HADEN GUEST, M.C., M.R.C.S. ENG., L.C.C.,
SECRETARY AND PHYSICIAN TO THE BRITISH LABOUR DELEGATION.

I.—EPIDEMIC DISEASE.

THE visit of the British Labour Delegation to Russia extended from May 10th, when we entered that country at the Russo-Esthonian frontier (near Narva), to June 15th, when we recrossed it on our return. During that period I visited Petrograd for a few days and Moscow for about a fortnight. From Moscow we went to Nijni-Novgorod, on the Volga, where we embarked on a beautiful Volga steamer, the s.s. *Bielinski*, and with the red flag of the Republic, with its R.S.F.S.R. printed in bold letters across its width, fluttering at the prow, sailed down to Astrakhan, on the Caspian Sea, returned thence to Saratoff, and so back by train to Moscow, Petrograd, and out to Esthonia.

During the time I was in Russia I was able to see hospitals and other medical institutions in Petrograd, Moscow, Saratoff, Astrakhan, and other places (small towns and villages on the Volga), and see them in freedom. I talked freely with medical men and women, sometimes in English, more often in French, and even occasionally I stuttered a little German. Only a few doctors are definitely Communists, but practically all doctors (like all others, in fact) are working for the Communist Government. The medical service in Petrograd is under the direction of Dr. Pervouchen; the medical service of the whole of Russia and Siberia, civilian and military, is under the medical control of the Minister of Health (called in Russia the Commissar of Public Health), Dr. Semasko, whose headquarters are at Moscow.

Dr. Semasko is a man of about 43 years of age with a serious, kindly face, a simple and courteous manner, and a real grip of the work he has in hand. Dr. Semasko is a Communist by party, but he is, of course, a man of trained scientific mind, a mind which tries to see facts as they are; he does not wish to exaggerate or to conceal facts. He spoke to me and to my friends with an admirable directness and precision. Some of our conversations were carried on in French and some (for the benefit of those not understanding that language) in Russian through an interpreter chosen by the Labour Delegation from among a non-Communist political group. My notes of conversations were made at the time, and I was supplied also with answers to a questionnaire I put in, and with copies of the official reports published by the Commissariat of Health.

Health Conditions: Absence of Necessities.

There is no doubt that the health conditions in Russia are extremely bad. Great epidemics of cholera, typhus, relapsing fever, Spanish influenza, and minor epidemics of other diseases have occurred, but all have been vigorously combated by the health authorities. Despite the handicap of an almost complete absence of soap, disinfectants, and drugs of all kinds, good work has been done. The figures quoted are those given to me officially, and although one cannot pretend that they are very accurate (registration and notification cannot be relied on), they are sufficiently accurate to give a clear idea of the extent of the epidemics. The population of Russia and Siberia is now estimated at 125,000,000, as the Baltic States and Poland are cut off on the West, and the Far Eastern Republic is the new boundary to the east of Lake Baikal. The whole of the rest of the area of Russia and Siberia, with the exception of Georgia in the south, is one country for practical purposes, although there are political differences in regard to the degree of nearness of affiliation of the Azerbaijan Republic, Turkestan, and so on.

In 1918 there was an epidemic of *cholera* reaching 35,619 cases, which should be compared with the previous epidemic of more than 200,000 in 1908. Credit for this limitation is certainly due to the Commissariat of Health. In 1918 also over 700,000 cases of Spanish *influenza* were registered and a special research

instituted to study this disease, the report of which is expected shortly.

Measures taken against Typhus.

In the autumn of 1918 *typhus* appeared in epidemic form and became more widespread in the spring of 1919. 1,299,262 cases were registered in the eight months up to July, 1919, with a death-rate of 8 to 10 per cent. This epidemic particularly affected the cities where food conditions were worst. The typhus died down during the summer, but broke out again in October, November, and December, 1919, the increase coinciding with the advance of the Red Army into Siberia, all the districts evacuated by Koltchak being infected. When the epidemic died down in the East, after heroic measures of burial of corpses and disinfection had been undertaken, it broke out again in the south, again coinciding with the advance of the army into an infected region occupied by Denikin.

DR. SEMASKO,
Commissar of Public Health for all Russia and Siberia.

The measures taken to combat the disease were as follows:—

(1) Cleanliness campaign in army, in towns and in villages by posters and handbills, and by enlisting groups of men, and particularly women, as volunteers to pay house-to-house visits as a propaganda of cleanliness. Much magnified pictures of the louse greet one in public places with sentences such as "The louse is the enemy of the Revolution," and simple explanations of the danger of these parasites. At Petrograd at a theatre where I happened to go the programme contained a note on the danger of lice and instructions to leave the hairy peasant coats a good many people wear in the cloak-room. "Cleanliness weeks" are used as concentrated propaganda, and everyone has to clean and scour, soap being then provided.

(2) One hundred and twenty-five control stations have been established on the railway lines in East and Central Russia providing for disinfection (by steam or formalin or sulphur, but not adequate), for medical inspection, removal of suspicious cases, a bath, hair cut with clippers, and a change of linen. The latter, however, was very difficult to provide. Doctors are always in attendance at these control stations. Total capacity of control stations 6578 per diem. Hospital accommodation is provided near the control stations.

(3) Provision of a special coach on each train for the reception of suspicious cases or definitely diagnosed cases of typhus. This applies to every line in Russia and Siberia.

(4) Medical inspection of military and civilian passengers at railway junctions.

(5) Provision of baths for army at the front—140 in all, with a daily capacity of 148,000 persons. These baths are arranged with entrance-room, washing-room, and dressing-room in three compartments to avoid reinfection. Most baths are of douche type, but some are slipper.

(6) Provision of baths for civilians. (A simple bath-house is common in peasant houses, and a weekly bath is customary.)

Generally speaking, there is enough public bath accommodation in the big towns, capitals of provinces (Gubernias) and their district subdivisions, but only one public bath as a rule for a group of two or three villages (Volost).

An Estimate of their Efficacy.

The figures of typhus for this year enable one to form an estimate of the effect of these measures.

Typhus in All Russia and Siberia in 1920.

(a) Civilians—		(b) Army—	
February ...	389,858	January ...	66,113
March ...	513,624	February ...	75,978
April ...	158,308	March ...	57,251
May ...	28,000	April ...	16,505

* Invasion of South—Denikin contacts.

When I visited hospitals in Petrograd, Moscow, Saratoff, and other places there were still large numbers of cases under treatment, but they were diminishing. Dr. Semasko told me that practically every town and village in Russia was infected, and I certainly found this was so at the numerous places where I inquired. A typical example of the condition of affairs was at Beresnaki, on the Volga, a place visited on June 2nd, 1920, and where I went over the hospital entirely on my own initiative. The population of the village was 13,000 (villages in Russia are large agglomerations of people), the hospital was of about 80 beds, a clean, well-kept place. I saw 20 typhus cases in the wards (June 2nd, 1920), about half men and half women. Careful precautions as to wearing a special long gown were insisted upon before entering the wards. The doctor told me there had been about 1000 typhus cases in the village in the winter and about 2000 in the surrounding district. Only 250 were provided with hospital accommodation. This village is in the Saratoff Province, and the doctor (who had had typhus) informed me that 14 per cent. of the doctors of the province had died from the disease. The figures given me in this village probably refer to typhus and to relapsing fever combined, and may include a few typhoid cases as the Russians use the term typhus in common for these three maladies, adding exanthematicus, recurrens or abdominalis.

The figures given me by Dr. Semasko for Russia and Siberia are for typhus only, but an approximately equal number of cases of relapsing fever occurred. There are, however, not (comparatively) many cases of typhoid fever. In Petrograd in May there were about 30 to 40 civilian cases of typhus a day, and about the same number of military cases. The figures for the week May 1st to 7th supplied to me by Dr. Pervouchen from his weekly return (interview May 13th) were typhus 363 cases, relapsing fever 69 cases, typhoid 7 cases. There were also 13 cases of small-pox and 54 of Spanish influenza, as well as other infections in smaller numbers—viz., very acute enteritis 8, dysentery 10, erysipelas 9, measles 2, scarlet fever 2, diphtheria 2. The cases to which these figures refer were those removed to hospital only.

Cholera.

The epidemic in 1918 has already been referred to and in 1919 there were only a few cases. In January of this year there was cholera in 10 places, chiefly in the South of Russia. In one of these, Saratoff, on the Volga, there were 26 cases, in all the others there were 430 cases. By March the number of cases had fallen to 216. The day I left Moscow, May 14th, I heard (not officially, however) that there were 100 cases of cholera in the town. Vivid picture propaganda showing the path of infection of cholera in its different stages—the sick man,

washing of linen in river, drinking of unboiled water, &c.—was to be seen very frequently, and the poster was easy to understand whether one could read the words or not. It is to be sincerely hoped that there is not a severe epidemic this summer, as with the increased traffic on the Volga now that fighting with Denikin is over it will spread much more easily. Also the way is now open to the east via the Caspian Sea.

Small-pox.

From Nov. 1st, 1918, to July, 1919, there were 81,851 cases registered. In December, 1919, there were 147 cases; January, 182; February, 149; March, 72. Vaccination was made compulsory by decree on April 16th, 1919, and carried out extensively. The Commissariat of Public Health claims to have abolished the disease.

There has been no especially severe epidemic affecting children, and only an occasional sporadic case of plague has occurred, originating from the endemic centre on the Steppe to the east of Astrakhan. Tuberculosis has increased, syphilis has very much increased, especially in the south, where the country has been traversed by invading armies.

(To be continued.)

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Austrian Physicians in Russian Captivity: Projected Exchange.

A CONSIDERABLE number of physicians and surgeons hailing from the districts of present-time Austria are still prisoners of war in Siberia. These unhappy men, many of them captured as early as 1914-1915, were never allowed the privilege of returning home when their hospitals were broken up, but they had to continue their work in other parts of the vast country. Even after the formation of the new states by the upheaval of the old Austro-Hungarian Empire, these purely Austrian doctors had to do service amongst Czecho-Slav, Hungarian, Yugo-Slav, or Italian prisoners of war in Asia, whilst medical officers of these nations were sent home. The medical organisation of Vienna has taken up the matter, and has appealed to the profession for volunteers to change places with the men absent from home and family for so long. About 220 men are needed for exchange, which, for political reasons, has hitherto been impossible. It appears that the obstacles have now been removed, and those doctors who have volunteered to go abroad and relieve their homesick brethren have been advised to keep themselves ready for departure at short notice.

American Physicians' Grants for Austrian Physicians.

Professor Pirquet, head of the paediatric clinic in Vienna, formerly a Johns Hopkins professor at the University of Baltimore, has received from an American Relief Committee consisting of practitioners a cheque for \$10,000, to be spent on distributing articles of food to University lecturers and theoretical teachers of medicine in Vienna. Professor Pirquet has fulfilled this wish, at the same time making the grant a means of a scientific research. All persons applying for a gift from this grant were examined as to their nutritional condition according to the "nem" system¹ of Pirquet. It was found that on an average children of the applying families lacked 1-3 kilonem (1000 nem), adults 2-3 kilonem daily in the quantity of food allotted to them by the State and obtainable by the food-tickets. The deficit was provided from the American grant. On an average each family received 154 kilonem per month, and the quantity of food for disposal was estimated as sufficient to last four months. Two hundred families were thus assisted, and after three months exact weights and measurements were taken. It was found that 128 families showed increase of weight, ranging from 4 kg. to 8 kg. per person—proving how greatly

¹ Nutritional value of 1 g. of milk.

underfed these families were. In one case of a family—a father, mother, and two children—the increase was uniform, being 3·3 kg. each after two months only. The food distributed consisted chiefly of white flour, rice, lard, corned beef, and condensed milk in tins. Pregnant women, as well as wet-nurses, received an extra ration of five tins of milk per month. In this way the \$10,000 were made to serve the real object for which they were collected.

Increase of Females in the Higher Schools.

The reports of the Board of Schools for the last half year shows a constant increase in the number of girls entering the so-called middle schools, or gymnasia, where Latin and Greek are taught as a preliminary to the examinations for university study. Whilst the boys are taking up more practical vocations—there was a drop of 8 per cent. in the male entries to these schools last year—girls seem to be more and more willing to take up a university career, and their entry has increased by 40 per cent. We have now co-education here, boys and girls being taught in the same classrooms, and the teachers assert that the girls are much more bright and alert than the masculine material the teachers are dealing with at present. This observation should be read along with the account of under-feeding. The increase of female medical students, as well as students of chemistry, has been noteworthy during the last two years.

August 18th.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

The Indian Red Cross.

At the outbreak of the war no Red Cross organisation as such existed in India. Red Cross work was carried on, in addition to its normal activities, by the St. John Ambulance Association in India until August, 1916, when the Indian Branch of the Joint War Committee was established on the model of the Joint War Committee in England, being a combination of the British Red Cross Society and the Order of St. John of Jerusalem. At this time the combined associations had no separate funds, but were relying on moneys collected by the St. John Ambulance Association and on grants made by the Joint Committee in England. The administrative importance of the Indian Branch of the Joint War Committee was duly recognised in 1917. Collections resulting from "Our Day" appeal enabled relief to be sent to Mesopotamia, East Africa, Egypt, and latterly to the North-West Frontier of India. It is proposed to devote the balance of the funds to the relief of sickness in civil life. The Indian Red Cross Society, which has just come into being, occupies the same position as that of the British Red Cross in the International League of Red Cross Societies. It was considered advisable for the Joint War Committee, which had the backing of all shades of responsible Indian opinion, to establish an independent Indian Red Cross Society, with branches in every province and with functions expanding beyond war work in co-operation with the work of the St. John Ambulance Association and Brigade. With a view to widening as far as possible the field of useful work opening to the Indian Red Cross Society and to the provincial branches the Indian Red Cross Act legalises affiliation with bodies having cognate aims and objects.

Leper Menace in India.

A report has been issued on the work accomplished in India last year by the Mission to Lepers. It is very encouraging, the appeals to Indians having met with substantial support. During the year a number of lepers were discharged from the homes as symptom-free. It is too early to say if they are cured, but there is hope for early cases if they persist in the treatment. The introduction of the Bill for the amendment of the Leper Act marks an epoch in the attitude of the Indian Government to the leper. It is hoped that this measure will be passed during the ensuing session, as its urgency is universally admitted. The original Act provides for the segregation of pauper lepers and control of those

following certain callings. In practice it is a dead letter. It has proved of little service, since the police, whose duty it is to take pauper lepers before a magistrate, do not like touching persons suffering from leprosy. Again, a leper in an asylum may leave when he likes. He cannot be detained after his open sores are healed, though he is still a leper and a potential danger to the public. Under the new Bill it will be possible for provincial Governments to segregate compulsorily begging lepers in settlements where they can be carefully looked after and their disease treated by the most modern methods.

Child Welfare in India.

The success attained by the Child Welfare Exhibition at Delhi has been repeated in various other Indian towns where similar entertainments have been organised. It is worthy of record that the total number of persons who visited Delhi were over 50,000, of whom 40,000 were women. These women were drawn from all classes, and their interest was most gratifying to those who assisted in organising the exhibition. The attendance at the women's lectures was so large that it was necessary to charge a small fee to prevent overcrowding. There were 1500 entries for the baby show.

Calcutta Water-supply.

Calcutta has been suffering acutely from a deficient supply of unfiltered water. The old sanitary arrangement, in which the "Mehlei" played so important a part, has disappeared, and the householder is dependent upon the municipality for a supply of unfiltered water for flushing purposes. Much hardship has ensued from the fact that no unfiltered water was to be had on first storeys, and remonstrances were sent to the Water Department without result. It is now announced that the Calcutta Corporation Commissioners have adopted the scheme drawn up by Mr. R. St. George Moore for the improvement of the water-supply.

Sanitation in the Punjab.

The Punjab Sanitary Board has approved of several important drainage systems for the province, and is doing excellent work in organising sanitary effort of every kind and the diffusion of instruction in elementary hygiene throughout the Punjab.

MEDICINE AND THE LAW

Patent Medicines as an Investment.

A PILL manufacturer, summoned at Willesden for the non-payment of rates, complained—we have the authority of *Punch* for August 25th in saying so—that the pill trade had fallen on evil days; "no ex-Service men seem to require pills." The circular, however, received by a member of our staff from a firm of stock-brokers, offering shares in a company, the object of which will be to deal in "specifics" and "remedies," contains a reminder that "profits running into millions of pounds have been made in patent medicines." And the brokers go on to say that their investigations convince them that "huge dividends will be earned and paid on the small capital of £—," concluding that "no investment to-day can possibly offer better prospects." Possible investors may perhaps do well to bear in mind that the prospect of patent medicines as a source of huge dividends may be diminished by the Proprietary Medicines Bill, if it should become law in anything like its present form. How far the Act will affect the sale of proprietary medicines of a harmless character can hardly be foreseen. If it passes in its present form some diseases will be placed beyond the reach of the medicine vendor, and would-be remedies likely to cause injury to health will be removable from the proposed register by administrative order. The sale of medicines containing alcohol and dangerous but unscheduled drugs will also presumably be the subject of regulation and control. The advertising of medicines, not in themselves injurious, by methods of an objectionable character, and likely to mislead the purchaser, will also be stopped to a large extent. The use of fictitious testimonials, the advertisement of a medicine as being recommended by an unnamed medical

practitioner, or as being the invention or discovery of a doctor when this is untrue will be forbidden. Methods of this kind have in the past swelled the "huge dividends" of patent medicine vendors, and raised their profits to millions of pounds. *Punch*, in a poem based upon the pill-manufacturer's complaint, which we began by quoting, puts the matter thus:—

"Meanwhile you'll understand that I, for one,
Refuse to buy your wares and eat them just for fun,"
which is the common-sense view.

Certificates under the National Health Insurance Acts.

The Minister of Health, acting upon the report of the Inquiry Committee of the London Insurance Committee, has ordered that £50 be withheld from the Exchequer grant to the committee, to be recovered under Article 33 of the Regulations from a medical practitioner on the London panel. This heavy fine is inflicted in the following circumstances. The practitioner had given certificates in the usual form, stating that he had examined the patient on the dates named in them in respect of a patient whom he had not in fact visited for some time. He was aware that the patient had returned to his home from an infirmary in October, 1919, and gave the certificates up to January, 1920, when the patient died. It was not disputed that the patient was during this period incapable of work, or that in the practitioner's opinion he could never be otherwise. The penalty is a heavy one, but it must be remembered that it was in the power of the Minister to remove the practitioner from the panel, and that to furnish a certificate at variance with the facts is not only a breach of the regulations, but is wholly unjustifiable in principle. A medical certificate of incapacity which states that a patient has been seen by the certifier is evidence from a trusted witness that he is alive and entitled to sickness benefit. A man may be certainly and inevitably dying, but the fact of his being beyond question alive is important, and if fraud is rare and difficult to perpetrate it is not impossible or inconceivable. One of the allegations made against our admittedly faulty system of death registration is that it does not effectively prevent burial without the presentation of the prescribed certificate, and that a certificate obtained for one person can thus be kept and used for another whose death has not been registered. Such fraud may be neither frequent nor easy, but in so far as it can occur, it would render possible the payment of sickness benefit in respect of a person who was dead. That no fraud should have been perpetrated or dreamt of by anyone in a particular case does not detract from the importance of certificates relating to sickness or death being absolutely accurate and trustworthy.

A Coroner on Expert Anæsthesia.

An inquest held lately upon the body of a young woman who died under chloroform was the occasion for interesting comment on the part of the coroner. The medical features of the case were not, so far as the scanty details available show, unusual and merely enforce the well-known lesson that anæsthetics have special danger in the presence of acute cellulitis of the neck. In the case in question the anæsthetic was administered by a casualty officer, and the coroner stated that owing to the dangerous nature of operation for cellulitis of the neck it would have been better if one of the visiting anæsthetists could have been in charge. This is a counsel of perfection. It is an unfortunate but unavoidable anomaly of hospital practice at present that many of the most dangerous and difficult subjects for anæsthesia fall into the hands of the less experienced administrators. They are subjects for emergency operation and have to be treated when the expert anæsthetists are away from the hospital. It can hardly be otherwise unless there is always at the hospital a resident anæsthetist, as there is at many hospitals a resident surgeon. Most of the great hospitals now do possess a resident anæsthetist, and often he is a man of wide experience compared with that of the other residents. Further progress may ensure the constant presence in large hospitals of an anæsthetist whose standing is on a par with that of the resident surgeon or physician.

URBAN VITAL STATISTICS.

(Week ended August 21st, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 9.9, 9.6, and 9.4 in the three preceding weeks, rose to 9.9 per 1000. In London, with a population of nearly 4½ million persons, the annual death-rate was 9.8, or 1.3 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 3.9 in Hornsey, 4.0 in Swindon, and 4.3 in Ealing to 15.4 in South Shields, 15.7 in West Bromwich, and 16.0 in Burnley. The principal epidemic diseases caused 204 deaths, which corresponded to an annual rate of 0.6 per 1000, and comprised 129 from infantile diarrhoea, 35 from diphtheria, 17 from whooping-cough, 16 from measles, 5 from scarlet fever, and 2 from enteric fever. Measles caused a death-rate of 1.6 in Wolverhampton, but the mortality from the remaining epidemic diseases showed no marked excess in any of the large towns. There were 2150 cases of scarlet fever and 1362 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 2106 and 1413 respectively at the end of the previous week. The causes of 27 of the 3394 deaths in the 96 towns were uncertified, of which 8 were registered in Birmingham, 4 in Liverpool, and 3 in South Shields.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 11.2, 11.1, and 12.3 in the three preceding weeks, fell to 10.8 per 1000. The 235 deaths in Glasgow corresponded to an annual rate of 11.0 per 1000, and included 11 from infantile diarrhoea and 1 each from scarlet fever and whooping-cough. The 75 deaths in Edinburgh were equal to a rate of 11.5 per 1000, and included 3 from scarlet fever and 2 from diphtheria.

Irish Towns.—The 106 deaths in Dublin corresponded to an annual rate of 13.3, or 0.2 per 1000 above that recorded in the previous week, and included 5 from infantile diarrhoea and 1 from whooping-cough. The 68 deaths in Belfast were equal to a rate of 8.6 per 1000, and included 4 from infantile diarrhoea and 1 from whooping-cough.

(Week ended August 28th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 9.6, 9.4, and 9.9 in the three preceding weeks, was again 9.9 per 1000. In London, with a population of nearly 4½ million persons, the annual death-rate was 9.7, against 9.8 per 1000 in the previous week, while among the remaining towns the rates ranged from 3.7 in Edmonton, 3.9 in Hornsey, and 4.9 in York, to 16.8 in South Shields, 17.2 in Stockton-on-Tees, and 17.5 in West Hartlepool. The principal epidemic diseases caused 237 deaths, which corresponded to an annual rate of 0.7 per 1000, and comprised 150 from infantile diarrhoea, 34 from diphtheria, 23 from measles, 20 from whooping-cough, 9 from scarlet fever, and 1 from enteric fever. The deaths from infantile diarrhoea, which had been 87, 93, and 129 in the three preceding weeks, further rose to 150, and included 38 in London, 13 in Liverpool, 9 in Birmingham, and 1 each in Sheffield and Hull. There were 2266 cases of scarlet fever and 1391 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 2150 and 1362 respectively at the end of the previous week. The causes of 34 of the 3395 deaths in the 96 towns were uncertified, of which 8 were registered in Birmingham and 3 in Liverpool.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 11.1, 12.3, and 10.8 in the three preceding weeks, rose to 11.1 per 1000. The 270 deaths in Glasgow corresponded to an annual rate of 12.7 per 1000, and included 16 from infantile diarrhoea, 6 from small-pox, 2 from enteric fever, and 1 each from measles, scarlet fever, and whooping-cough. The 77 deaths in Edinburgh were equal to a rate of 11.8 per 1000, and included 2 from infantile diarrhoea and 1 from diphtheria.

Irish Towns.—The 122 deaths in Dublin corresponded to an annual rate of 15.3, or 2.0 per 1000 above that recorded in the previous week, and included 4 from infantile diarrhoea, 2 each from whooping-cough and diphtheria, and 1 from enteric fever. The 105 deaths in Belfast were equal to a rate of 13.3 per 1000, and included 8 from infantile diarrhoea and 1 each from scarlet fever and diphtheria.

THE Médaille de la Reconnaissance Française (argent) has been conferred by the President of the French Republic on Mrs. Bedford Fenwick, honorary superintendent of the French Flag Nursing Corps.

REGISTRABLE COLONIAL AND FOREIGN MEDICAL DEGREES.

UNDER the Medical Act, 1886, a number of medical diplomas granted in British possessions entitle their holders to be registered without further examination in the Colonial List of the (British) Medical Register. The condition attached to such registration is that the holder of the colonial diploma obtained it when he was not domiciled in the United Kingdom or in the course of a period of not less than five years during the whole of which he resided out of the United Kingdom. Some account is here given of these diplomas and of the course of study required to obtain them. The information has in most cases been supplied or confirmed by the authorities of the university or corporation, to whom our best thanks are offered.

AUSTRALASIA.

Summary of Registrable Degrees.—New South Wales: University of Sydney, (1) M.B., (2) M.D., (3) Ch.M. New Zealand: University of New Zealand, (1) M.B., Ch.B., (2) M.D. South Australia: University of Adelaide, (1) M.B., B.S., (2) M.D., (3) M.S. Victoria: University of Melbourne, (1) M.B., (2) M.D., B.S.

University of Adelaide.

The University of Adelaide¹ was established by Act of the South Australian Legislature in 1874. In 1883 Sir Thomas Elder gave £10,000 for the foundation of a school of medicine. The Medical Acts of 1844 and 1880 set up a South Australian Medical Board to issue certificates of legally qualified medical practice.

Preliminary Examination.—Before entering upon the medical course candidates must have passed the Senior Public Examination in at least five subjects, and the higher standard in physics, chemistry, and biology, either of the Higher Public Examination or first year Science.

M.B., B.S.—The five years' course includes five examinations held in November of each year. At the first the subjects are anatomy and dissections, physiology, organic chemistry, and physical chemistry; at the second, anatomy, physiology, and materia medica; at the third, medicine, surgery (including clinical), regional and surgical anatomy, bacteriology; at the fourth, medicine (including clinical), surgery (including surgical anatomy and clinical surgery), pathology, obstetrics, and forensic medicine (including insanity); at the fifth, medicine (all branches), surgery (including surgical anatomy and operative surgery), gynaecology, ophthalmology, otology, therapeutics, and public health and preventive medicine. The fee for each examination is £3 3s. and for the degree £5 5s. Fees for the five years' course of study amount to £145 19s. There were 96 undergraduate students in 1919.

M.D.—Candidates must have been Bachelors for at least nine academic terms, which may be shortened on the recommendation of the Faculty of Medicine. The subject of examination may be selected from the following: General medicine, diseases of the nervous system, pathology, obstetrics, State medicine. A thesis may be submitted. Fee for the examination £15 15s., for the degree £10 10s.

M.S.—The conditions are similar to those for the M.D. Choice of subject may be made from: Gynaecology, the surgery of the abdomen, the surgery of the special senses and throat; in addition to examination in the principles of surgery.

University of Melbourne.

The University of Melbourne² was incorporated by Act of the Victorian Legislature in 1853. The Medical Act of 1890, substantially amended in 1906, set up the Medical Board of Victoria to register legally qualified medical practitioners.

Preliminary Examination.—All candidates must possess the School Leaving Certificate, which is based on education in a secondary school during four years. The Intermediate

Certificate must have been taken at least a year before the School Leaving. English is compulsory at the higher standard; Latin and geometry with trigonometry at the lower.

M.B., B.S.—The course extends over five calendar years, and is divided into two equal parts, hospital practice being confined to the second half. The first year (Division I.) is devoted to natural philosophy, chemistry, zoology, and botany; the remainder of the first half (Division II.) to anatomy and physiology. Two complete courses of dissections are compulsory. Hospital practice extends through Divisions III. and IV. The general hospitals ranking as clinical schools are the Melbourne Hospital, the Alfred Hospital, and the St. Vincent's Hospital. The recognised special hospitals include the Women's Hospital, the Children's Hospital, the Eye and Ear Hospital, the Infectious Diseases Hospital, the Receiving House, and Acute Mental Hospital. A full clinical curriculum is arranged, both general and special, with clinical lectures. In Division III. (lasting one year) courses of lectures are given in pathology (with practical work in histology and in bacteriology), in therapeutics, public health, materia medica and pharmacy, and regional and applied anatomy, and examination in all these subjects follows immediately. In Division IV., lasting a year and a half, systematic lectures are confined to the first year and include medicine, surgery, and forensic medicine. Lectures on obstetrics and gynaecology are given in Division III., but the examination in these subjects is postponed till the final at the end of the course, which also includes the subjects of Division IV. Clinical medicine and clinical surgery rank as separate subjects in the finals.

Honour examinations with exhibitions are held in all subjects of Divisions I., II., and III., and there is a final honour examination with scholarships in medicine, in surgery, and in obstetrics and gynaecology.

The yearly fee payable to the University is £23, with a sports fee of 1 guinea and a club-house fee of 1 guinea. The hospital and pharmacy fees in Divisions III. and IV. amount to £69 6s. The total fees are £194 16s. The degree fee for M.B., B.S., is 7 guineas.

The number of students for the full course now in attendance is 732. Provision is also made for instruction to dental students, massage students, single subject students, &c.

M.D.—Candidates must be Bachelors of Medicine of two years' standing. They may proceed either by thesis or by examination. The thesis must be a substantial contribution to medical knowledge. The examination includes medicine, with either obstetrics and medical gynaecology, or diseases of children, or diseases of the nervous system, including insanity. Subject to a dispensing power in the case of theses of great merit, all candidates must pass an examination in clinical medicine. The fee for examination and degree is 10 guineas.

M.S.—Candidates must be Bachelors of Surgery of two years' standing. Part I. of the examination includes surgical anatomy and surgical pathology. Part II. includes surgery in all branches. The two parts may be taken together or separately. No candidate can pass in Part II. who has not passed in Part I. The fee for examination and degree is 10 guineas.

Diploma of Public Health.—Granted under conditions agreeing with those in the United Kingdom. Fees for instruction are 32 guineas, apart from fever hospital practice. The fee for examination is 10 guineas, for diploma 3 guineas.

Diploma of Tropical Medicine.—Candidates must be qualified medical practitioners, and must have passed Part I. for D.P.H. or have undergone a special training in lieu thereof. They are trained in tropical medicine at the Australian Institute of Tropical Medicine, Townsville, Queensland, having a three months' course of theoretical and practical instruction, followed by a three months' clinical course in the Townsville Hospital. The examination is conducted at the institute. Fee for preliminary course is £2 2s.; for course at institute, 10 guineas; for examination and diploma, 5 guineas.

Affiliated Colleges.—Trinity College (1872), Ormond College (1879), Queen's College (1888), and Newman College (1918) are affiliated to the University and have medical tutors.

¹ The University Registrar is Mr. C. R. Hodge. The Calendar of the University of Adelaide (1920) is a volume of 534 pp., printed by W. K. Thomas and Co., Grenfell-street, Adelaide. Price 2s. 6d.

² The University Registrar is Mr. J. P. Bainbridge, J.P. The Melbourne University Calendar (1920) is a volume of 1111 pp., printed for the University by Ford and Son, Drummond-street, Carlton, Melbourne. Price 3s.

University of New Zealand.

The University of New Zealand was established by Act of the New Zealand Legislature in 1870. The Medical Act of 1908 provided for the registration of medical practitioners. The University has no fixed home or buildings; it is an examining body with four affiliated colleges—namely, University of Otago, Dunedin; Canterbury College, Christchurch; Auckland University College; and Victoria University College, Wellington. The degrees of M.B., Ch.B., M.D., and B.D.S. are conferred, and the subjects of study are Biology, Physiology, Medicine and Surgery, Ophthalmology, Chemistry, Bacteriology and Public Health, Anatomy, Pathology, Midwifery and Gynaecology, and Dentistry. The agent in England is J. W. Joynt, Esq., M.A., 11, Torrington-square, London, W.C. 1.

University of Sydney.

The University of Sydney³ was incorporated by Act of the New South Wales Legislature in 1850. The Medical Practitioners Act of 1898 provides for the registration of legally qualified medical practitioners.

Matriculation Examination.—Latin and another language other than English are required, one at the Higher standard.

M.B., Ch.M.—The course of study extends over a period of five years. Five degree and a final examination are held: (1st year) in physics, chemistry, botany and zoology; (2nd year) in anatomy and physiology; (3rd year) in the entire subjects of anatomy and physiology, every part of the body having been dissected at least once; (4th year) in pathology, surgical anatomy and operative surgery, materia medica, and therapeutics; (5th year) in medical jurisprudence and public health; (final) in medicine, surgery, obstetrics, and gynaecology. Certificates of proficiency in vaccination and anaesthetics are required. The fee for each degree is £10. The number of students attending degree courses during 1919 was 876—783 men and 93 women.

M.D.—Candidates must, after obtaining the degree of Bachelor, have spent at least two years in medical or surgical practice or in approved study. Examination is written or oral in one of the following subjects: medicine, medical jurisprudence and public health, surgery, obstetrics and gynaecology; or in any of the scientific subjects included in the medical curriculum. A thesis must be presented two months before the examination. The fee for the degree is £10.

Diploma in Public Health.—Candidates must be registered practitioners of not less than 12 months' standing. The examination is in two parts: (1) relating to the general principles of sanitary medicine; (2) relating to State medicine and to the applications of pathology and sanitary science to public health. The fee is £10.

Affiliated Colleges.—Matriculated students are admitted to the following resident colleges—namely, St. Paul's College (Church of England), St. John's College (Roman Catholic), St. Andrew's College (Presbyterian), Wesley College (Methodist), the Women's College (undenominational), at which scholarships and bursaries are available.

Recognised Hospitals are the Royal Prince Alfred Hospital with medical school, the Sydney Hospital with clinical school, St. Vincent's Hospital, the Royal Hospital for Women, the Royal Alexandra Hospital for Children, the Glandesville and Callan Park Hospitals for the Insane, the Women's Hospital, the Renwick Hospital for Infants, and the South Sydney Hospital for Women.

BRITISH NORTH AMERICA.

Summary of Registrable Degrees and Diplomas.—Alberta: College of Physicians and Surgeons, Member. Manitoba: College of Physicians and Surgeons, Member; University of Manitoba, M.D., C.M. New Brunswick: Provincial Council of Physicians and Surgeons, L.M.S. Newfoundland: Medical Board, L.M.S. North-West Territories: College of Physicians and Surgeons, Member (when held in conjunction with the licence of Alberta or Saskatchewan). Nova Scotia: Provincial Medical Board, L.M.S.; Dalhousie University, M.D., C.M. (Halifax Medical College, M.D., C.M., if obtained prior to August 31st, 1911). Ontario: College of Physicians and Surgeons, Member.

³ The University Warden and Registrar is Mr. H. E. Barff, M.A. The Calendar of the University of Sydney (1920) is a volume of 740 pp., printed for the University by Angus and Robertson, Ltd., Sydney. Price 2s. 6d.

(To this can be added as additional qualifications the degrees in medicine of the Queen's University, Kingston; the Western University, London; and the University of Toronto.) Prince Edward Island: Medical Council, L.M.S. Quebec: McGill University, M.D., C.M.; Laval University, M.D. Saskatchewan: College of Physicians and Surgeons, Member.

Dalhousie University, Halifax, Nova Scotia.

The work of Halifax Medical College was discontinued in 1911, when instruction in all subjects of the medical curriculum was undertaken by Dalhousie University. The professional examinations are conducted conjointly by the university and the Provincial Medical Board of Nova Scotia (see below).

M.D., C.M.—In addition to the matriculation or preliminary examination candidates are required to pass five professional examinations. For admission to the classes of the third or any higher year the undergraduate must have passed in all the subjects of the preceding year. The curriculum for the third year still includes practical anatomy and advanced physiology, while the fifth (final) year subjects are given as: Surgical anatomy, operative surgery, clinical surgery, clinical medicine, clinical pediatrics, clinical obstetrics, practical obstetrics, clinical gynaecology, mental diseases, skin diseases, eye, ear, nose and throat diseases, dressing, clerking, vaccination, post mortems, hospital, medical ethics. To win distinction in any subject a mark of 75 per cent. or over is required. The total tuition fees in any year amount to \$125, with \$10 additional for the third, fourth, and fifth years. The fee for each examination is \$10. There were 160 medical students of all years in 1919–20. Dean of the Faculty, John Stewart, M.B. Edin., LL.D. Edin. and Dal.; Secretary, Professor Fraser Harris, M.D., D.Sc.

Queen's University, Kingston, Canada.

Queen's College, Kingston,⁴ was established by Royal charter in 1841, assisted by grants from the Presbyterian Church in Scotland. Classes in medicine were first held in the University in 1854. The Medical School, conducted for a time under the charter of the Royal College of Physicians and Surgeons at Kingston, became an integral part of the University in 1892. Kingston General Hospital (230 beds) is adjacent to the University buildings.

M.D., C.M.—Candidates for a degree must pass the Junior Matriculation of the University or its equivalent. The course comprises five sessions of eight months each. A combined B.A. and M.D. course may be taken in seven years. Foreign students must spend at least one full session in the University. Examinations are held at the end of each session. The average cost per session of eight months, including board and lodging, is \$376–\$435. All students are expected to attend a church of the denomination to which they profess to belong.

D.Sc.—Granted on a thesis embodying original research of importance to medical science not earlier than two years after graduation. A reading knowledge of scientific French and German is required.

D.P.H.—The diploma is granted to those holding the M.D., or M.D., B.Sc., after examination following prescribed study, which includes six months with a recognised medical officer of health in the study of practical sanitation.

Laval University, Quebec.

Laval Catholic University⁵ was incorporated by Royal Charter in 1852, absorbing the Quebec School of Medicine organised four years earlier. The first class graduated in 1855.

M.B., M.D.—The entrance examination includes Latin, philosophy, and Canadian history, and its standard is prescribed by the College of Physicians and Surgeons of Quebec. The Faculty of Medicine confers a baccalauréat and a doctorat, the former after 2 years, comprising 6 terms of study, the latter after 3 further years. Examinations are held in June at the end of each year of study. The total fee for examinations is \$15, for the diploma of bachelor \$5, and for that of doctor \$20. Fees paid by enrolled students for the medical course amount to \$45 a term.

⁴ The Secretary of the Medical Faculty is Dr. A. R. B. Williamson, Queen's University, Kingston, Ont.

⁵ The Medical Department of Laval University was destroyed by fire on Nov. 24th, 1919, and is now in process of rebuilding. The Secretary of the Medical Faculty is M. Arthur Vallée.

McGill University, Montreal.

The Faculty of Medicine of McGill University⁶ arose out of the Montreal Medical Institution, organised as a medical school in 1823-24, and incorporated in the University in 1829.

Preliminary Examination.—Before registration an undergraduate in medicine must have passed the Matriculation Examination of the University or its equivalent. The examination is held twice yearly at McGill, and once at Calgary, Regina, Winnipeg, Toronto, St. John, and Truro. Also in June in London (apply to Secretary, Headmasters' Conference, 12, King's Bench Walk, E.C.). Latin, and either Greek, French, or German must be taken. Every student entering the University is required to pass a physical examination to detect defects and weaknesses amenable to treatment. Board and lodging can be obtained in private houses in the vicinity of the University at \$40 a month upwards.

M.D., C.M.—The undergraduate course in medicine has this year been increased to six years by a pre-medical year devoted to chemistry, physics, and biology, with English and one modern language. This readjustment gives a final year confined to hospital work, including medicine, surgery, obstetrics, gynaecology, ophthalmology, oto-laryngology, pathology, and dermatology. The third year now embraces anatomy (neurology), physiology, general pathology, bacteriology, chemistry (physiological and clinical), parasitology, pharmacology, and clinical microscopy. During this year students begin to visit the hospitals and receive instruction in small groups in the elements of clinical medicine and clinical surgery. Examinations are held in the subjects of each successive year. The total faculty fees for the medical course of six years are \$1200, payable in twelve instalments of \$100 each. The degree fee is \$30. 624 medical students were enrolled in the session 1919-1920.

D.P.H.—This course, cancelled during the war, has now been resumed.

New Brunswick, Council of Physicians and Surgeons

The Council of Physicians and Surgeons of New Brunswick is empowered by the Medical Act to issue a licence (L.M.S.) conferring the legal right to practise. The usual matriculation examination is required and the graded collegiate course comprises five sessions of not less than eight months each. The examinations are held twice a year at St. John, N.B., the fee being \$30. Candidates may appear for the primary examination at the end of the second year of study. The fee for the licence is \$3 and the registration fee \$40. The registrar of the council is Dr. S. Skinner, 64, Charlotte-street, St. John, N.B.

Nova Scotia, Provincial Medical Board.

A licence (L.M.S.), legally entitling to practise, is issued by the Provincial Medical Board of Nova Scotia to those who have satisfied requirements in respect to preliminary and professional education. After registration in the Medical Students' Register (fee \$25) a course of at least five full years in medicine must be taken. Graduates of medical schools recognised by the Board who can submit satisfactory schedules of studies are admitted to the third (final) professional examination (fee, including registration, \$75). All applicants for registration must take this examination except licentiates of the General Medical Council of the United Kingdom and of the Medical Council of Canada, who are admitted to registration without examination upon payment of a fee of \$50. The registrar of the Board is Dr. W. H. Hattie, Halifax, N.S.

University of Toronto.

The University of Toronto,⁷ Ontario, took its title in 1849, a Royal Charter having been granted in 1827. The Faculty of Medicine was re-established in 1887 under the Federation Act. Victoria College (1892), Trinity College (1904), and St. Michael's College (1907) are integral parts of the University.

Preliminary Examination.—The matriculation certificate of the University is required from entrants unless they are graduates in Arts of a Dominion or British University or

possess a certificate of entrance into the Faculty of Education.

M.B.—The undergraduate course has just been lengthened to six years. Six examinations are taken in succession at the end of the session. The early years aim at giving such a training in sciences as is now exacted of those who desire to obtain a British as well as a Canadian qualification. During the third year an attempt is made to bridge the gap between the primary scientific and the final clinical subjects by taking up anatomy and physiology at the same time as surgery and medicine throughout the year. Preliminary courses in pathology and pathological chemistry are taken; instruction is given in pharmacology; and a series of ten lectures delivered on psychology. The final year includes courses on anaesthesia, dentistry, medical ethics, history of medicine, and life insurance. The annual fee for regular students with one annual examination is \$150. Combined courses of B.A., M.B. and B.Sc., M.B., lasting seven years, are also arranged. Honour standing can be obtained in each year's subjects. There is residence for about 150 men and three houses near to the University. Each male student proceeding to a degree must take physical training, the character to be determined by medical examination in the first two years of his attendance.

M.D.—One year must elapse after obtaining the M.B. degree and an approved thesis submitted.

D.P.H.—Candidates must be graduates in medicine of this or some other University. The curriculum extends over a winter session of eight months and a summer session of three months. The fee for the course is \$150 and for the diploma \$20.

NEAR EAST.

Registrable Degrees.—University of Malta, M.B., Ch.B., M.D., Ch.M.

University of Malta.

The University of Malta was added in 1898 to the list of institutions recognised by the English Royal Colleges. Study in the Faculty of Medicine and Surgery⁸ is open to matriculated students who have attended a three years' preparatory course in the Faculty of Science. Matriculation includes English, Italian, and Latin, while history is also necessary to comply with the G. M. C. regulations. The preparatory course in science in its third year comprises English or Italian literature, physics, organic chemistry, and human anatomy and general histology, with dissection. Medical botany is taught at the Botanic Garden. The academical course of medicine and surgery (*M.B., Ch.B.*) extends over four years, the first year being devoted solely to anatomy and physiology, and the final year including clinical medicine, surgery, and midwifery, along with skin diseases, mental diseases, operative surgery, and forensic medicine, and continued attendance at the clinical laboratory and the hospital. The degree of *M.D.* or of *Ch.M.* is conferred on any *M.B., Ch.B.* on passing an examination at not less than one year after graduation, in each case with an approved thesis. The fee for any of the three degrees is £6.

FAR EAST.

Summary of Registrable Degrees.—Ceylon: Medical College, L.M.S. Hong-Kong: University of Hong-Kong, M.B., B.S. India: University of Allahabad, M.B., B.S.; University of Bombay,⁹ (1) L.M.S., (2) M.B., B.S., (3) M.D., (4) M.S.; University of Calcutta, (1) L.M.S., (2) M.B., (3) M.D., (4) M.S., (5) M.O.; University of Madras,¹⁰ (1) M.B., M.S., (2) M.B., B.S., (3) M.D.; Punjab University, (1) L.M.S., (2) M.B., (3) M.D., (4) M.S. Straits Settlements: King Edward VII. Medical School, Singapore, L.M.S.

University of Allahabad.

The examination for the degree of *M.B., B.S.* consists of three parts: preliminary scientific, first degree, and final degree. The two latter are held at Lucknow. The preliminary scientific examination in chemistry, physics, and biology is open to candidates who have passed in these subjects at the intermediate examination of the University. The first degree examination comprises anatomy, physiology,

⁶ The University registrar is Mr. J. M. Nicholson. *M.A.* The registrar of the Faculty of Medicine is Dr. J. W. Scane. The Annual Calendar of the Faculty of Medicine and Department of Dentistry is a volume of 90 pp., printed by the Gazette Printing Co., Ltd., Montreal.

⁷ The Secretary of the Faculty of Medicine is Dr. E. S. Ryerson.

⁸ Statute of the University of Malta, 1915, Government Printing Office, Malta, price 1s.

⁹ If obtained after June 25th, 1912, the degree must have been registered in the Presidency.

¹⁰ If obtained after June 1st, 1916, the degree must have been registered in the Presidency.

and materia medica and pharmacy; it may be taken after two years. The final degree examination comprises two groups: (A) midwifery, hygiene, and medical jurisprudence, taken after two years; (B) medicine, surgery, and pathology, taken a year later. Honours may be obtained in any subject. The *M.D.* and *M.S.* degrees are obtained within not less than one year on passing an examination in medicine and pathology. The fees for the *M.B.*, *B.S.* examination are Rs.140, for the *M.D.* and *M.S.* Rs.200 each.

King George's Medical College, Lucknow, prepares students for the medical degrees of the University of Allahabad. The curriculum extends to five college years, each of three terms. Scholarships and bursaries are granted.

*University of Bombay.*¹¹

Candidates for the *M.B.*, *B.S.* must have passed the first year arts examination or its equivalent, and be engaged during five University years in professional study at a medical college recognised by the University. Three examinations are held: the first, or preliminary scientific; the second, or intermediate; and the third, or final; each of them twice in the year. The two former are of the usual character. The final is divided into two parts, which may be taken together or separately two years after the intermediate. Part I. includes medicine, medical jurisprudence, pathology, and hygiene; Part II. surgery, midwifery, and ophthalmology. 561 medical undergraduates passed examinations in 1919-20. Candidature for the degrees of *B.Hy.*, *M.D.*, *D.Hy.*, or *M.S.* implies that the *M.B.*, *B.S.* degree has been taken not less than three years (*B.Hy.*, one year) previously.

Grant Medical College, Bombay, was established in 1845, to "teach the system of Western medicine and to extend the benefit of Western medical instruction to the Natives of Western India," and recognised by the University in 1860. Attached is a laboratory for scientific medical research. The students are arranged in three classes: (1) graduates and undergraduates of the University of Bombay and other recognised Universities who are educated through the English language for medical degrees; (2) members of the European and domiciled European communities who are educated through the English language for the grade of military assistant surgeon; (3) undergraduates and others for the diplomas of the College of Physicians and Surgeons, Bombay.

*University of Calcutta.*¹²

For the degree of *M.B.* the preliminary scientific, first, and final *M.B.* examinations must be passed. The final is divided into two parts, major and minor, which may be taken together. The former includes medicine, surgery, and midwifery; the latter general pathology, medical jurisprudence, and hygiene. An examination for honours is held a week after the pass list is declared. The fees for the three examinations are Rs. 25, Rs. 30, and Rs. 50 respectively. The *M.D.* degree is granted after examination in medicine, pathology, and mental diseases not less than one year subsequent to the *M.B.* The fee is Rs. 100. Degrees of Master of Surgery (*M.S.*) and Obstetrics (*M.O.*) are also granted. A diploma in public health is granted to possessors of the *M.B.* degree or *L.M.S.* diploma by examination after a prescribed course of a year has been carried out. The fee is Rs. 100.

Ceylon Medical College.

The Ceylon Medical College¹³ began in 1870, and the curriculum and examinations were revised in 1901 in conformity to modern requirements. In 1888 the licence in medicine and surgery (*L.M.S.*) granted by the College was recognised by the General Medical Council of the United Kingdom. Lady students were first admitted in 1892. There are two department in the College—viz., Medical and Apothecary. For admission to the Medical Department of the College candidates must pass Cambridge Senior Local or Senior School Certificate Examination or the London

Matriculation Examination in the required subjects. The first professional examination is passed at the end of the first year, the second at the end of the third, the third at the end of the fourth, and the final at the end of the fifth. The fifth year's course includes, besides the usual final subjects, instruction in tropical medicine, skiagraphic demonstrations, and attendance at fever and leper hospitals. The total fees for the medical curriculum, including examination fees, amount to Rs. 1423.50. Various scholarships and medals are awarded by Government and private donors.

University of Hong-Kong.

The Faculty of Medicine of the University of Hong-Kong (1912) had its origin in the work of the Hong-Kong College of Medicine founded in 1887. The School of Anatomy was opened in 1913 and special schools for physiology, pathology, and tropical medicine were opened in 1918 and 1919. The University confers the degrees of *M.B.*, *B.S.*, *M.D.*, and *M.S.* The subjects of the first medical examination are physics, chemistry, and biology; of the second, Part I., anatomy, physiology, Part II., general pathology (including bacteriology), and elementary pharmacology; of the third, Part I., surgery and midwifery, Part II., medicine and pathology, including hygiene and tropical medicine. The fee for each part of each examination is \$5, and for conferring the *M.B.*, *B.S.* \$25. The candidate for *M.D.* may present himself in two years and must take general medicine as well as one of the following: State medicine, pathology, midwifery, tropical medicine, physiology. The rules for *M.S.* are similar. The fee for each examination is \$100 and for conferring the degree \$100. The acting Registrar of the University is Mr. K. Brayshaw, B.A.

University of Madras.

A medical school was established in Madras in 1835, which became the Madras Medical College in 1851 and was affiliated to the University in 1877. The College was originally for supplying assistant surgeons and hospital assistants to the army, but now undertakes also the training of students for the medical degrees and diplomas of Madras University. Candidates for the degrees of *M.B.*, *B.S.* must have passed the Intermediate Examination in Arts of the University or its equivalent, and have studied medicine for not less than five years in a college affiliated to the University. Four examinations are held, the third (at the end of the third year) comprising general pathology and hygiene, and the fourth the other professional subjects. The examination fees are Rs.25, Rs.25, Rs.40, and Rs.50 respectively. The *M.D.* degree may be taken not less than one year after a first-class pass in either medicine, midwifery, pathology, or tropical medicine. The conditions for the *M.S.* degree are similar. The examination fee in each case is Rs. 100. A degree in sanitary science (*B.S.Sc.*) can be taken in two parts one year after the *M.B.*, *B.S.*, the total fee being Rs.100.

The *Madras Medical College* includes a college department, an apothecary department, a chemists' and druggists' department, and a sanitary inspectors' department. The course of training for the *M.B.*, *B.S.* is charged Rs. 120 a year, or a lump sum of Rs.540 if paid in advance. Valuable scholarships are awarded by the Government and by the Dufferin Fund, and special Government stipends to women medical students.

Punjab University.

An examination for the degree of *M.B.*, *B.S.* is held annually in Lahore in May, and consists of three parts—first, second, and final. The first professional examination is open to candidates who not less than two years previously have passed the intermediate examination of the Science Faculty taking the medical student's group; it comprises anatomy, physiology, and materia medica, and the fee is Rs. 30. The second examination is in pathology, forensic medicine, and hygiene, and is taken at the end of the third year; the fee is Rs.30. The final examination, for which the fee is Rs. 40, is taken at the end of the fifth year and comprises the rest of the professional subjects.

King Edward Medical College, Lahore, trains students for the medical degrees and diplomas of Punjab University. The college year consists of one long session of three terms. The course for the *M.B.*, *B.S.* occupies five years, the fees being Rs.125, Rs.115, Rs.135, Rs.105, and Rs.105 in successive years. College scholarships are granted.

¹¹ The Registrar of the University is Mr. K. B. F. M. Dastur, M.A. The Bombay University Calendar (1920) vol. 1 is a volume of 662 pp., printed at the Government Central Press, Bombay.

¹² The University of Calcutta Regulations (1913) make a volume of 410 pp., published by the University. The Calendar is a volume of 814 pp., also published by the University.

¹³ The Registrar of the college is Dr. P. J. Kelly. The Ceylon Medical College Calendar (1919-20) is a volume of 38 pp., published by authority and printed by H. R. Cottle, acting Government printer, Colombo.

REGISTRABLE FOREIGN MEDICAL DEGREES.

Certain medical diplomas granted in foreign countries also entitle to registration in the foreign list of the Medical Register, provided that the holder is not a British subject or that, being a British subject, the diploma was obtained under domiciliary conditions similar to those attached to colonial diplomas.

Summary of Registrable Degrees (the date in parentheses being the year in which Part II. of the Medical Act, 1886, was applied to the country in question).—*Italy* (1901): Degrees of Doctor of Medicine and Surgery of all the Royal Italian Universities. *Japan* (1905): Degrees of Bachelor of Medicine (Igakushi) and Doctor of Medicine (Igaku Hakushi) of the Imperial Universities of Japan; and the Degree of Bachelor of Medicine (Igakushi) of any Government or Prefectural special medical college, or of a private special medical college designated by the Minister of Education of the Empire of Japan. *Belgium* (1915): Degrees of Doctor of Medicine of the Belgian Universities of Brussels, Ghent, Liège, and Louvain, which give legal authority to practise medicine, surgery, and midwifery in Belgium.

Italy.

The regulation for the medical diploma is fixed by Royal Decree dated August 9th, 1910, and is the same for each of the 20 universities and institutes where courses of study are arranged. These are in alphabetical order: Bologna, Cagliari (Sardinia), Camerino, Catania, Ferrara, Florence, Genoa, Messina, Modena, Naples, Padua, Palermo, Parma, Pavia, Perugia, Pisa, Rome, Sassari,¹⁴ Siena, and Turin.

The course covers six years, and embraces the following 20 constituent subjects: (1) experimental physics, (2) inorganic and organic chemistry, (3) botany, (4) zoology and comparative anatomy, (5) normal human anatomy (descriptive or systematic, macroscopic and microscopic), (6) physiology, (7) general pathology, (8) pharmacology and toxicology, (9) pathological anatomy and histology, (10) special medical (practical) pathology, (11) special surgical (practical) pathology, (12) medical clinics, general and special, (13) pediatric clinic, (14) surgical clinic, general, special and operative, (15) obstetric and gynaecological clinic (16) ophthalmological clinic, (17) clinics of nervous and mental diseases, (18) hygiene and public health, (19) legal medicine, (20) dermatological and venereal clinic.

The distribution of these subjects over the six years varies somewhat at the different centres, but the official course at Siena may be taken as an example:—1st year: botany, zoology, normal human anatomy. 2nd year: normal human anatomy, general chemistry, experimental physics, embryology, experimental physiology. 3rd year: normal and topographical human anatomy, experimental physiology, bacteriology, general pathology. 4th year: materia medica, special medical and surgical pathology, pathological anatomy, medical and surgical clinic. 5th year: pathological anatomy, medical, surgical, ophthalmological, and dermatological clinic, hygiene and public health. 6th year: medical, surgical, nervous and mental, pediatrics, and obstetric clinic, legal medicine, operations, history of medical science. Twenty-six optional courses in special subjects can be attended by students of various years. The examinations are held in the latter half of October and June.

Japan.

The medical course is taken at the Imperial Universities of Kyoto and Tokyo, and at the medical schools of Formosa, Aichi, Chiba, Kanazawa, Kumamoto, Nagasaki, Okayama, and Sendai.

The *Kyoto College of Medicine*¹⁵ was established in 1899. It includes institutes of anatomy, physiology, medical chemistry, pharmacology, pathology, hygiene, forensic medicine, medicine, surgery, ophthalmology, gynaecology, pediatrics, dermatology, oto-rhino-laryngology, orthopaedic surgery, and psychiatry, each in charge of one or more of the 22 professors and 16 assistant professors, the director being Dr. Hayazo Ito. There is a four years' course of instruction, the first year being devoted to anatomy, histology, physiology, medical chemistry, and embryology. In the second year pharmacology, general pathology, pathological anatomy and histology, diagnosis, special medicine, general

surgery, and bandaging are added. The first examination is held at the end of the second academic year, the second at the end of the fourth year in surgery, medicine, ophthalmology, gynaecology, and either hygiene or forensic medicine (the choice being determined by lot). At request students are also examined in pediatrics, dermatology, oto-rhino-laryngology, psychiatry, and orthopaedic surgery. In the year 1919 79 students graduated in medicine from the College.

Belgium.

The medical course for the degree of M.D. may be taken at any of the four Universities: Free University of Brussels, State University of Ghent, University of Liège, Catholic University of Louvain. After a preliminary year and an examination which may be taken in two parts—(1) logic, zoology, botany; (2) physics, chemistry, geology—the student becomes "candidat en sciences naturelles." Two years are then devoted to the ancillary sciences, the examination again being in two parts—(1) embryology, systematic anatomy Part I., histology, comparative anatomy, physiology; (2) systematic anatomy Part II., regional anatomy, special histology, psychology, special physiology—when the stage of "candidat en médecine" is reached. Professional studies occupy three years at least, and there are three further examinations. The first includes (i.) general pathology and therapeutics; (ii.) elements of pharmacology and pharmacodynamics; (iii.) pathological anatomy; (iv.) general surgical pathology. The second includes: (i.) medical pathology and special therapeutics, including mental diseases; (ii.) special surgical pathology; (iii.) public and private hygiene; (iv.) the theory of accouchement. The third and final comprises (i.) legal medicine, (ii.) medical clinic, (iii.) surgical clinic, (iv.) operations, (v.) ophthalmological clinic, (vi.) obstetric clinic, as well as practical tests in pathological microscopy and regional anatomy.

The Universities of Ghent and Liège grant a diploma of "médecin-hygiéniste" after examination to medical graduates of at least one year's standing.

University of Liège.—The Faculty of Medicine includes 15 professors and eight lecturers. The dean is Professor L. Fredericq (Institut physiologique). The fee for inscription in the medical faculty is Fr. 200 for the grade of candidate and Fr. 200 for each of the three parts of the professional examination. The Dean of the Medical Faculty is Dr. F. Fraipont. Details of the courses may be obtained from Professor Ch. Julin, secretary to the medical faculty.

University of Louvain.—All the courses in the Faculty of Medicine have been resumed. For the third professional examination the programme is as follows: A. Lemaire (medical clinic), R. Schoekaert (theory of accouchement), A. Vander Straeten (ophthalmological clinic), R. Bruynoghe (legal medicine), G. Debaisieux (surgical clinic), L. Van den Wildenberg (oto-rhino-laryngological clinic), A. Van Mosuencq (dental clinic), O. De Mees (minor surgery). The dean of the faculty is Professor Schoekaert, and the secretary Professor Bruynoghe (rue Marie Thérèse 100).

University of Brussels.—The former courses in the Faculty of Medicine were resumed in January, 1919, as well as the clinics at St. Jean and St. Pierre, and the instruction for the diploma of public health.

Details of these courses may be obtained from the secretary of the University at rue des Sols 14, Brussels.

HEALTH OF BLACKPOOL.—The annual report for the year 1919 by Dr. E. W. Rees-Jones, medical officer of health for Blackpool, contains interesting observations on social conditions in that town. The infantile mortality rate decreased from 110.5 in 1918 to 96.8 in 1919, while the high general death-rate of 15.5 was considered as still due to the aftermath of war. On the housing question Dr. Rees-Jones says:—

"Basement dwellings constitute one of the most unsatisfactory features in Blackpool, and it is highly desirable that the corporation should have legal powers to prohibit, except by special registration, the use of basements as separate tenements. While some of the front basements in houses facing south might be considered suitable for the purpose, the back basements are very unsuitable, being badly lighted and ventilated. Constant supervision also is necessary to prevent overcrowding and other insanitary conditions arising from the action of the tenants, and 316 visits were paid by the sanitary inspectors."

Dr. Rees-Jones comments on the disadvantages of the production and distribution of milk by private enterprise, and looks forward to the time when the municipality will organise and control the milk-supply.

¹⁴ Dean of the Medical Faculty, Professor Ottorino Rossi.

¹⁵ The *Kyoto Imperial University Calendar* (1919-20) is a volume of 174 pp., published by the University.

Correspondence.

"Audi alteram partem."

THE RETURN OF THE DISABLED SOLDIER TO CIVIL LIFE.

To the Editor of THE LANCET.

SIR,—The national scheme for the employment of disabled ex-Service men set out to "secure and maintain the complete absorption of all disabled men into industry." Its achievements have been remarkable, but it is now apparent, after some 18 months, that there remains in the country a residue of disabled men who are unemployable in ordinary industry, "a residue for whom no provision at present exists—namely, those who possess some potential capacity, but could only exercise it if some special arrangements were made for enabling them to do so." (See White Paper 185, p. 9, "Employment.")

Some recent figures, or lack of figures, may throw light upon the extent of the problem of war disablement which has still to be faced.

(1) Wholly disabled, at their homes or in institutions	?
(2) The tuberculous, the epileptic, and blind	?
(3) Still in hospitals	say 60,000
(4) Disabled men still under concurrent treatment and training, shortly to be increased to 4400 (Minister of Pensions, <i>Times</i> , August 16th)	2,200
(5) Disabled under training by the Ministry of Labour (Minister of Labour, <i>Times</i> , August 12th)	24,000
(6) Disabled awaiting such training (<i>ibid.</i>)	21,700
(7) Disabled officers, &c., under training (White Paper, p. 1)	5,000
(8) Disabled, registered as requiring employment (Minister of Labour, House of Commons, July 22nd)	22,000
(9) Disabled already absorbed into industry— Officers, &c. (White Paper, p. 1)	9,301
Men (Minister of Labour, <i>Times</i> , August 12th)	176,000

What is this "residue" referred to in the White Paper? It is made up of a considerable proportion of "seriously injured" who are now registered for employment, together with a large number of men who are from various reasons not so registered. The residue is being continually reinforced from Classes 3, 4, 5, 7, and 9. There must always be a proportion from the large numbers of men who are being absorbed into industry, who break down and return under medical care, and although the disabled men training under the Ministry of Labour (5) are supposed to be fit to work alongside of normal men, experience shows that here, too, a certain proportion break down.

The approximate numbers of the subnormal may be computed from the figures already given and from my own experience of different categories of disablement at the Enham Village Centre. The men at Enham were no doubt rather more disabled than those usually sent to convalescent centres. A few had lost a limb, more were partly paralysed by injuries to limbs. Many others were permanently affected by injuries to the head, either definite wounds or shock, resulting in many forms of disturbance—mental irritability, depression and anxiety, fits and crises of various kinds. Others had been gassed, and remained, at all events for some time, unfit for ordinary work. Others were hampered by heart affections and rheumatism and chronic infections, like malaria and dysentery.

Excluding all who were likely to pass out and take up ordinary employment with a fair hope of success, as well as a small number of men incapable of useful work, I found a remainder, amounting to nearly 20 per cent., whom we placed in a special category as "subnormal." Taking the country as a whole, one subnormal in ten disabled would be a safe minimum estimate. It may well be considerably more. On this basis there cannot be less than 25,000 ex-Service men in the country who are at present unfit for ordinary conditions of industry, but who yet possess a good capacity for work. What is to be their future? Many whom I have seen have shown their keenness by trying work again and again, and have broken

down.¹ At present these weakened workers, often of fine character and capacity, have no prospect of employment under the only conditions that are possible for them. The apprehension, depression, and bitterness of mind resulting from such a position can be readily imagined. When they leave the treatment and training centre, or break down after taking employment, they are the despair of the local committees and of the people who are trying to set them on their feet. We must except the fine work being done by the Lord Roberts workshops, where a limited number of men, chiefly injured in the right arm, and therefore unable to compete in the open market, are given permanent paid employment, according to their ability. But these workshops are unfortunately inadequate to deal even with their own class of cases. Following Earl Haig's recent appeal, a certain number of the men we have in mind will probably be given employment by charitable persons, but if experience be any guide it is not likely to be permanent. If to the above 25,000 be added the tuberculous and the epileptic, who are in the same unprovided condition, the total of the subnormal is indeed a disquieting one.

Two recommendations are made by the Parliamentary Committee in the White Paper:—

(1) "That special attention be given to the cases of men who, though not requiring treatment, and therefore not eligible for the convalescent centres, need some form of training or employment in special workshops, or under special conditions, in order to exercise their earning capacity, and that such arrangements be made for them as may be found to be necessary."

(2) "That special attention be given to the desirability of establishing disabled men who have received agricultural training on cottage holdings."

But surely the injured worker must de facto remain an object of medical care, especially in the early stages of employment, and this often means "treatment," mental or physical. He cannot continue in the convalescent centre after his "training" is completed, nor is it advisable that he should do so. His one desire is to be settled, and if married to have his family about him. Treatment must therefore follow him into his new life. As regards (2), it may be of interest to note that in France the existence of this class of subnormal men is a less difficult problem, owing in great measure to the system of land tenure. Investigation shows that the great majority of such men appear to have returned home and to be working on their own small piece of land. They are, as in England, unfit to do a full day's work, either in industry or on the land, but they are perfectly capable of doing their two, three, or four hours a day on their land, thus eking out a slender living with the help of their pensions and their friends. Their health and earning capacity are meanwhile improving under conditions of quiet and freedom from care. The great proportion of these subnormal men in France, as in England, are nerve-strained, and for them such conditions are essential.

What proportion of subnormal men in our country are likely to find their vocation on the land? I should say not more than 1 in 4. The majority either have not the necessary physical strength or the inclination for agriculture or horticulture. Many have their occupations—as printer, colour-etcher, photographer, book-binder, furniture-maker, shoemaker, tailor—and they have no desire to give them up. What they want is the opportunity to carry them on under proper conditions in the country. A man can work at his trade two or three or six hours daily instead of eight, but only in a quiet atmosphere. Given these conditions, his skill is as good as ever. In his spare time we shall find him in his garden or allotment.

Special conditions of life and supervision are obviously needful, not only for the men just described, but for the seriously injured now under training, as well as for the many who are falling out of the ranks of industry. A very clear distinction ought to be drawn between the temporary care of disabled men away from their homes in treatment and training centres, and the permanent care of the residue of subnormal men with their families

¹ Mr. H. L. Rothband (*Times*, August 21st) quotes the testimony of many large employers, that disabled employees are usually anxious for work and are "keener and more conscientious" than the others.

in communities. The first task has been taken over by the Government. The second has yet to be accomplished. Is not this the time for private organisations and friends of the disabled all over the country to coöperate with the Government in organising and administering assisted industries for these weaker brethren? It cannot be done by machinery alone. Much individual care, skilled supervision, and above all the right atmosphere are necessary to give these men a chance, as well as the new special study of the adjustment of vocation to mental and physical capacity. I have seen the power of work return in apparently hopeless cases under the right handling. Many men labelled "subnormal" regain their full earning capacity. Many others will always need the sheltered life.

My experience at Enham has convinced me that all types of partial disablement ought to be mingled together in these village communities, because the interaction of different points of view is favourable to health and morale. And I earnestly hope that the medical service in these communities will include both mental and physical methods of treatment. To the medical profession at this juncture belongs the task of formulating what is needful for this large remnant of weakened and dispirited men, and putting before the public and the Government a remedy for a distressing state of affairs.—I am, Sir, yours faithfully,

London, August 29th, 1920.

R. FORTESCUE FOX.

THE TIME OF DAY TO GIVE ANTIMONY TARTRATE FOR BILHARZIA.

To the Editor of THE LANCET.

SIR,—In THE LANCET of August 21st (p. 392) Dr. F. G. Cawston, writing of intravenous injections of antimony tartrate, states:—

"Toxic effects are undoubtedly lessened where the injections are given shortly after a light breakfast, instead of later on in the day. This point has been emphasised by Dr. J. B. Christopherson."

In my article in the *Journal of Tropical Medicine and Hygiene* for July 15th, 1919, I did not exactly say this. I related there that one of the most intelligent of my patients, when injected early in the morning, 9.30 or 10 A.M., found the after-effects to be nil, whereas when the injections were given near lunch time, 12.30 or 1 P.M., he always had giddiness, vomiting, and the reaction generally was severe. "It would therefore appear," I said, "that injections should be given some considerable time, three or four hours, before meal-time." I was referring to natives in the hospital at Khartoum, who breakfast soon after 7 A.M. and lunch at 12-1 P.M.

The question of the best time for making the injections, from the point of view of the condition of the stomach and the digestive processes, is in my opinion a very important one. They should not be given when the stomach is full—for instance, just after a heavy meal—when the blood is largely engaged in the portal circulation with the process of digesting the meal, for, if given then, the toxic, depressing action of the drug will be emphasised, the pulse will possibly be slowed and become weaker, the face pinched and perhaps dusky, the pupils contracted. On the other hand, if given just before a meal, when the patient is depressed and perhaps faint for want of food, the toxic effects of the drug will also be emphasised, especially if a meal be taken directly after. This is shown by a feeling of giddiness, retching, perhaps vomiting, reaction generally. It seems only a matter of common sense that the drug, which has a tendency to depress, should not be given at the time when the patient naturally is depressed. The time of day in itself is not important.

But it is of practical importance, especially when dealing with out-patients, who are not under the same control as in-patients are, to tell them they must not engage in exhausting work previous to nor hurry to be in time for the injection, so that they either have no time for a meal or only time for a hurried scramble of bread and cheese and a glass or two of beer immediately before arrival. Therefore my advice to out-patients is to have a quiet morning. A little necessary work will not matter, but a light digestible meal must be arranged

two and a half or three hours before the injection is due. As a light meal I should, for example, advise a basin of good soup with toast or bread, a little fish, and a milk pudding. For a patient in Egypt, the Sudan, or South Africa some corresponding and appropriate food should be taken two and a half or three hours previous to the injection.

It is by attention to details such as these that success is to be attained.—I am, Sir, yours faithfully,
August 24th, 1920.

J. B. CHRISTOPHERSON.

GENERALISED HERPES OR CHICKEN-POX?

To the Editor of THE LANCET.

SIR,—The recent discussion in THE LANCET upon herpes and chicken-pox suggested that a case at present under my care may be of general interest.

My patient, a man 80 years old, spent four hours in the open air watching a cricket-match on June 26th. The next day he was suddenly seized with an acute pain over the outer side of the left leg, with definite tenderness along the course of the external popliteal nerve. I treated him for neuritis, but on June 28th his pain was only slightly less severe. On June 29th I noticed several small papules evenly distributed over the trunk, extending to the shoulders, arms, and back of both thighs. There was no rash on the face, forearms, or legs. The next day the rash had mostly become vesicular, but new papules had appeared with the same distribution with the addition of some over both legs. Over the outer side of the left leg there was also a fairly well marked erythema, which I then attributed to the effect of the liniment. Apart from this erythema, the appearance was indistinguishable from that of chicken-pox of moderate severity. On July 1st an intense herpetic eruption appeared on the left buttock and leg in two well-marked lines, corresponding probably to the cutaneous sacral nerves, and over the sole of the left foot in a single well-marked line corresponding to a possible cutaneous branch of the internal plantar nerve. The whole of the left leg was now painful, but the acute pain at the original site had diminished.

There was no doubt that the patient was now suffering from an attack of herpes zoster, and I recalled a paper by Dr. Cranston Low¹ on the possible association of varicella and herpes zoster. Six weeks after onset the patient still bears pitted marks, still complains of occasional shooting pains and hyperalgesia over the region of distribution. I must mention that previous to the onset of this illness, and commencing on June 14th last, the patient took in all half a drachm of liq. arsenicalis in m 2 doses three times daily after food as a general tonic. I cannot obtain any history of a previous attack of chicken-pox or shingles.

At present the question in my mind is whether this case has been one of varicella associated with herpes or one of "herpes zoster generalisatus," as described by Dr. Low.—I am, Sir, yours faithfully,

STEWART McNAUGHTON, M.D. Edin.,

D.P.H. Camb., &c.,

Honorary Physician, Monkwearmouth Hospital.

Sunderland, August 17th, 1920.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

THE following appointments have been made:—Surgeon Commanders: R. L. Jones to *Chatham*; P. H. Boyden to *President*, additional, for Porton Experimental Station; J. R. Muir to R.N. Hospital, Haslar; and R. H. McGiffin to *Raleigh*. Surg. Lieut.-Cmdr. W. H. Murray to R.N. Hospital, Gibraltar. Surg. Lieut. W. J. Colborne to 3rd R. M. Batt., Eastern Mediterranean. Surg. Cmdr. H. W. Finlayson is placed on the Retired List and granted the rank of Surgeon Captain.

ARMY MEDICAL SERVICE.

Major W. Davis relinquishes acting rank of Lieutenant-Colonel. Temp. Capt. D. C. McCabe-Dallas relinquishes acting rank of Major. Capt. J. M. Macfie to be acting Major. Temp. Major G. S. Simpson (Captain, R.A.M.C., T.F.) relinquishes his temporary commission on re-posting. Capt. F. Holmes, from Spec. Res., to be Lieutenant and to be temporary Captain. Temp. Major A. L. B. Green (Major, 1st Hereford R., T.F.) relinquishes his temporary commission. Capt. H. J. Bensted to be temp. Major whilst specially employed. The undermentioned to be temporary Captains: D. E. Hearn (late Captain, R.A.M.C., Spec. Res.), J. D. Judson (late temporary Captain), and H. H. McClelland (late temporary Captain). Major-Gen. Sir H. N. Thompson, half-pay list, retires on retired pay.

¹ Brit. Med. Jour., Jan. 25th, 1919.

Temp. Lieut.-Col. T. S. Good relinquishes his commission on ceasing to be employed at the Ashurst War Hospital, and retains the rank of Lieutenant-Colonel.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. H. W. K. Read, and Majors E. G. French (granted the rank of Lieutenant-Colonel), T. F. Ritchie retire on retired pay.
Temp. Capt. S. H. Pitcairn and J. L. Wilson relinquish the acting rank of Major.

Capt. D. Fettes (late temporary Captain, R.A.M.C.) and Temp. Capt. J. McP. MacKinnon and H. S. Moore to be Captains.
Temp. Capt. M. F. D. Graham to be Lieutenant and to be temporary Captain.

Lieut. A. M. Simson, from T. F. Res. (Art.), to be Lieutenant.
Officers relinquishing their commissions:—Temp. Capt. R. J. Monahan, M. J. Wilson, C. A. B. Horsford, E. C. Arnold, H. H. Perry, H. C. Sutton, W. L. G. Anderson, J. M. MacPhail, P. Johnson retain the rank of Captain.

SPECIAL RESERVE OF OFFICERS.

Officers relinquishing their commissions: Major H. G. Smeeth. Capt. R. E. Grandy, Capt. G. A. MacDonald (retains the rank of Captain). Capt. (granted the rank of Major) W. F. Wood, R. P. Starkie, S. J. V. Furlong, R. Taylor. Capt. (retaining the rank of Captain) A. B. Dummere, W. R. McLinden, R. R. Traill, M. Morrison, D. C. Rennie, W. McWilliam, H. L. Addison, H. J. Duske, T. L. Crawhall, A. Dick, T. B. Moves, F. J. Harvey, S. Adler, C. Young, Capt. A. A. Atkinson, F. Bignold, F. Randall, I. Evans. Lieut. A. Kennedy (retains the rank of Lieutenant).
Capt. A. Bulleid relinquishes the acting rank of Major.

GENERAL RESERVE OF OFFICERS.

Capt. H. J. Bower resigns his commission and retains the rank of Captain.

TERRITORIAL FORCE.

Capt. E. Scott (late temporary Captain, R.A.M.C.) to be Captain.
Capt. (acting Majors) M. Brennan, W. A. Brechin, and A. Cameron relinquish their acting rank on ceasing to be specially employed.

Officers relinquishing their commissions:—Major E. Turton and Capt. J. H. Peyton and C. S. Young are granted the rank of Lieutenant-Colonel.

Capt. J. Arthur, A. Oliver, W. Scott, D. M. Spring, T. W. Hancock, C. H. Bullen, and G. M. McGilivray are granted the rank of Major.

Capt. F. A. Pring resigns his commission.

Captains retaining the rank of Captain: J. E. Ransford, F. Ryan, S. Simpson, J. Fenton, H. W. Kerrigan.
Col. W. Ranson vacates the appointment of Assistant Director of Medical Services, East Lanes. Division.

Lieut.-Col. (Bt. Col.) F. H. Westmacott, from 2nd Western General Hospital, to be Colonel and Assistant Director of Medical Services, East Lanes. Division.

Capt. A. G. Wilson, from 3rd Northern General Hospital, to be Captain.

Capt. G. Eager (late temporary Captain, R.A.M.C.) to be Lieutenant, and to relinquish the rank of Captain.

Capt. J. G. Morrin (late temporary Captain, R.A.M.C.) to be Captain.

4th London General Hospital: Capt. A. J. Jex-Blake resigns his commission and is granted the rank of Major.

4th Northern General Hospital: Major W. E. F. Tinley resigns his commission and retains the rank of Major.

2nd Western General Hospital: Capt. J. Wharton resigns his commission and retains the rank of Captain.

2nd Eastern General Hospital: Capt. H. H. E. Scatiff resigns his commission and retains the rank of Captain, with permission to wear the prescribed uniform.

3rd Southern General Hospital: Capt. F. Clarke is restored to the establishment.

TERRITORIAL FORCE RESERVE.

Capt. H. G. L. Haynes to be Lieutenant-Colonel.

Major A. E. Hodder resigns his commission, and is granted the rank of Lieutenant-Colonel.

ROYAL AIR FORCE.

Medical Branch.—The undermentioned are transferred to unemployed list: Capt. W. G. Weston, J. D. Cherry, M. C. Breese, D. Cromie, Lieut. A. Wilson.

INDIAN MEDICAL SERVICE.

The King has approved the retirement of Lieut.-Col. W. H. E. Woodwright.

DECORATIONS.

Mr. E. S. Crispin, Director of the Soudan Medical Department and a Member of the Governor-General's Council, and Dr. A. F. Macallan, of the Ophthalmic Hospital, Egyptian Department of Public Health, have been appointed Commanders, and Dr. J. A. Clark, of the Medical Service of the Egyptian Army, has been appointed a Member of the Civil Division of the Most Excellent Order of the British Empire for services rendered in Egypt and the Soudan.

American.

Distinguished Service Medal.—Maj.-Gen. Sir W. B. Leishman, K.C.M.G., C.B., F.R.S., K.H.P.

Belgian.

Croix Civique.—1st Class: Lt.-Col. S. de C. O'Grady, C.M.G., D.S.O., R.A.M.C.

French.

Médaille de l'Assistance Publique.—"En Argent": Temp. Capt. H. O. Gough, R.A.M.C.; Lt.-Col. H. MacCormac, C.B.E., late R.A.M.C. "En Bronze": Temp. Capt. H. M. Agnew, R.A.M.C.; Temp. Capt. M. Eager, R.A.M.C.; Temp. Maj. T. N. Frood, R.A.M.C.; Temp. Capt. F. A. Ross, R.A.M.C.

Roumanian.

Order of the Crown of Roumania.—"Chevalier": Temp. Capt. M. Eager, R.A.M.C.

Medical News.

UNIVERSITY OF CAMBRIDGE.—The following have been reappointed Demonstrators: Biology, Mr. H. H. Brindley, St. John's; Animal Morphology, Mr. J. T. Saunders, Christ's; Comparative Anatomy, Mr. J. Gray, King's.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—L. Burvill-Holmes (Sects. I. and II.), Guy's Hosp.; M. C. Hartley (Sects. I. and II.), London Hosp.; H. Morris (Sect. I.), St. Bart's Hosp.; J. W. E. Ord (Sects. I. and II.), McGill; A. C. D. Telfer (Sects. I. and II.), St. Bart's Hosp.; and C. M. Tinkler (Sects. I. and II.), Liverpool.

Medicine.—J. A. Cohen (Sects. I. and II.), King's Coll. Hosp.; M. C. Hartley (Sects. I. and II.), London Hosp.; R. E. Jenkins (Sects. I. and II.), Charing Cross Hosp.; W. A. O'Connor (Sect. II.), Oxford and Birmingham; J. W. E. Ord (Sects. I. and II.), McGill; A. C. D. Telfer (Sects. I. and II.), St. Bart's Hosp.; and C. M. Tinkler (Sects. I. and II.), Liverpool.

Forensic Medicine.—B. C. Betts, Manchester; A. Y. Cantin, London Hosp.; J. L. Delicati, Bristol; M. C. Hartley, London Hosp.; W. A. O'Connor, Oxford and Birmingham; J. W. E. Ord, McGill; A. C. D. Telfer, St. Bart's Hosp.; C. M. Tinkler, Liverpool; and J. Solomonoff, London Hosp.

Midwifery.—A. Y. Cantin, London Hosp.; W. H. Cellier, Guy's Hosp.; R. Erskine Gray, Charing Cross Hosp.; C. T. Gasking, Liverpool and Sheffield; M. C. Hartley, London Hosp.; W. A. O'Connor, Oxford and Birmingham; J. W. E. Ord, McGill; J. Sulliman, Guy's Hosp.; A. C. D. Telfer, St. Bart's Hosp.; and E. W. Terry, Manchester.

The Diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery: L. Burvill-Holmes, A. Y. Cantin, M. C. Hartley, R. E. Jenkins, J. W. E. Ord, W. A. O'Connor, and A. C. D. Telfer.

Lord Southborough has been appointed chairman of the War Office Departmental Committee to inquire into the relation between shell shock and the death sentences for alleged cowardice in the earlier part of the war with a view to guidance in the future (see THE LANCET, May 8th, p. 1033, Parliamentary Intelligence).

RADCLIFFE INFIRMARY, OXFORD.—A post-graduate course will be held from Oct. 1st to 9th, which will include demonstrations of operations, medical cases, and cases in special departments in the mornings, whereas in the afternoon papers will be read by specialists of distinction, among whom will be the Regius professor, Sir Archibald Garrod, and Professor G. Dreyer. A dinner will be held in Queen's College Hall on Tuesday, Oct. 5th, at 7.30 p.m. (morning dress). The price of tickets is 15s., including wines, and they will be issued to those applying not later than Oct. 1st to Dr. Hugh Whitelocke, secretary to the committee, Radcliffe Infirmary, Oxford.

UNIVERSITY OF SHEFFIELD.—The University has recently founded a whole-time chair of pharmacology to which Dr. Edward Mellanby, at present professor of physiology in the University of London, has been appointed. Professor Mellanby has also been elected honorary physician to the Royal Infirmary in the place of Dr. W. S. Porter, who has resigned after 30 years' service. This direct connexion between the experimental study of pharmacology in the University and its clinical application to the treatment and investigation of disease offers a fruitful field for progress in this branch of medicine, and should lead to important results. Another interesting step is the appointment of Dr. J. B. Leathes, F.R.S., professor of physiology in the University, as honorary physiologist to the Royal Infirmary and the Royal Hospital. By arrangement between the University and the clinical institutions Professor Leathes and his assistants will have charge of clinical laboratories there, and will be responsible for all the chemico-physiological work required by the clinicians. From the point of view of clinical medicine this arrangement should prove of the highest value, and on the student's side it is a first step in the scheme evolved by the Faculty of Medicine to bridge over the gap between the early laboratory years and the later clinical stages of the student's curriculum. In outline this scheme consists (1) in holding the Second M.B. at the end of the second year in general anatomy and physiology; (2) in beginning clinical work in the third year, and continuing applied anatomy and physiology during the third and fourth years as subjects upon which, together with pathology and pharmacology, the student will be examined in the Third M.B. at the end of the fourth winter. Students will thus, during the middle third of their career, be doing clinical hospital practice and laboratory work in applied subjects simultaneously. It is hoped by this means to impress upon them that there are such sciences as anatomy and physiology of the living, upon which ultimately depend medicine, surgery, and pathology.

JOINT HOSPITAL ADVISORY COUNCIL IN SHEFFIELD.

—About a year ago the governing bodies of the four voluntary hospitals in Sheffield agreed to the formation of a Joint Consultative and Advisory Council, consisting of representatives of the boards and staffs of the Royal Infirmary, the Royal Hospital, the Jessop Hospital for Women, and the Hospital for Sick Children, together with representatives of the University, the Edgar Allen Institute for Medico-mechanical Treatment, and of the trades organisations of the city. The Lord Mayor is ex-officio President, and the Vice-Chancellor of the University (Sir Henry Hadow) was appointed chairman. The functions of the Council are, as indicated by its title, of a consultative and advisory character only, and although it has no direct control over any of its constituent bodies, it has already proved its value in bringing together all these hitherto distinct institutions, and enabling joint action to be taken in various matters of hospital policy submitted for its consideration. Many important questions have been investigated, and the Council is likely to prove of increasing utility in dealing with the difficulties with which all voluntary hospitals are faced. In Sheffield, as elsewhere, the immediate need of the voluntary hospitals is for increased funds to meet current expenses, and this subject is having the careful consideration of the Council.

THE Ministry of Agriculture is arranging to employ obsolete battleships as floating laboratories for the investigation of foot-and-mouth disease.

POST-GRADUATE LECTURES FOR PANEL DOCTORS.

The following post-graduate lectures will be held this autumn under the auspices of the London Panel Committee: A course on Laboratory Methods in the Prevention, Diagnosis, and Treatment of Disease will be given by Dr. W. W. C. Topley at Charing Cross Hospital on Thursdays at 4 P.M. (date to be announced later); and a course on Venereal Diseases, by Colonel L. W. Harrison, will be held at St. Thomas's Hospital commencing Thursday, Sept. 23rd, at 4 P.M. The fee for each course will be £3 3s., payable to the secretary of the Panel Committee at Staple House, 51, Chancery-lane, London, W.C.2, who will forward cards of admission.

ANNUAL DINNERS OF THE MEDICAL SCHOOLS.—For the convenience of past students of those of the London medical schools which are holding annual dinners in early October we append the following details as far as we have hitherto received them:—

St. Bartholomew's Hospital old students' annual dinner will be held on Friday, Oct. 1st, at 6.30 P.M. for 7 P.M. in the Great Hall of the Hospital. Sir Anthony Bowlby will preside. The honorary secretary is Sir C. Gordon Watson, 82, Harley-street, London, W.1.

Charing Cross Hospital Medical School annual dinner of past and present students will be held on Monday, Oct. 4th at 7 for 7.30 P.M., at the Adelaide Gallery, Gatti's Restaurant. Dr. J. Mitchell Bruce will take the chair. Past students requiring tickets are requested to write to the dean of the school.

St. George's Hospital Medical School annual dinner is to be held at Prince's Restaurant, Piccadilly, at 6.30 for 7, on Friday, Oct. 1st. Sir Humphry Rolleston will preside, and the honorary secretaries are Mr. Ivor Back and Dr. Claude Frankau.

King's College Hospital past and present students' dinner will be held on Friday, Oct. 1st, at 7 for 7.30 P.M., at the Criterion Restaurant, Piccadilly-circus, W. Dr. Philip Boobbyer will preside. Applications for tickets (price 15s., exclusive of wine) should be sent to the honorary secretaries, King's College Hospital.

St. Mary's Hospital annual dinner of past and present students will be held on Friday, Oct. 1st, at the Connaught Rooms, Great Queen-street, London, W.C., at 7 for 7.30 P.M. Sir John Goodwin will preside. Tickets (price 12s. 6d., exclusive of wine) can be obtained from the honorary secretary, Mr. V. Warren Low, 76, Harley-street, London, W.1.

Middlesex Hospital Medical School annual dinner will be held on Friday, Oct. 1st, at 7.30 P.M., at the Wharnccliffe Rooms, Great Central Hotel, Dr. R. A. Young in the chair. Those wishing to be present should communicate as soon as possible with the secretary-superintendent of the hospital.

Westminster Hospital old students' dinner will be held on Thursday, Sept. 30th, at the Imperial Restaurant, Regent-street, at 7.30 P.M. Lord Glenconner will be in the chair and the honorary secretary is Dr. Adolphe Abrahams.

University College Hospital Medical School annual dinner of old students will be held at the Imperial Restaurant, Regent-street, on Friday, Oct. 1st, at 7 for 7.30 P.M. Professor Harry Littlewood will preside. Tickets, price 15s. (not including wine), may be obtained from the honorary secretaries, Dr. A. M. H. Gray and Mr. Gwynne Williams, 30, New Cavendish-street, London, W.1.

MANCHESTER ROYAL INFIRMARY: OLD RESIDENTS' DINNER.—A notice of this dinner, which will take place on Oct. 9th, has been sent out to all members of the Old Residents' Club. Any members who have failed to receive one are asked to communicate with the honorary secretaries at the Royal Infirmary, Manchester.

HOSPITAL CONDITIONS IN MANCHESTER.—It is calculated that the expenditure on Manchester hospitals last year exceeded the income by about £30,000. The Manchester Royal Infirmary had a deficit of over £17,000, which, however, was considerably lessened by an opportune donation. The Ancoats Hospital had an overdraft of £9000, and the St. Mary's Hospitals for Women and Children a deficit on the year's working of nearly £7000. The Salford Royal Hospital is also spending £7000 more than its annual income.

INSTRUCTION IN HOSPITAL ADMINISTRATION.—A three months' course of lectures and demonstrations in hospital administration will be given at the Western Hospital, Seagrave-road, Fulham, S.W., by Dr. R. M. Bruce, on Tuesdays and Fridays, at 5 P.M., beginning Tuesday, Sept. 28th. Medical men desiring to attend should pay the fee for the course (£3 3s.) to the Clerk to the Metropolitan Asylums Board, Embankment, E.C., giving their full name and address, before the course begins.

A REPORT issued this week by the Commissioner of the Metropolitan Police shows that 688 persons were killed in street accidents in the metropolitan area during the year 1919, an increase of 76 over the fatal accidents of 1918. Of the total, private motor-cars accounted for 138 and motor-buses for 136. Tramcars, cabs, and motor-cycles were far behind with 42, 26, and 25 fatalities respectively.

SOCIETY FOR THE STUDY OF INEBRIETY.—A meeting of this society will be held in the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-street, W., on Tuesday, Oct. 12th, at 4 P.M., when, after consideration of the revised rules and by-laws submitted by the Council, Dr. James A. Davidson will open a discussion on "Special Clinics for Inebriates." Each member and associate is at liberty to introduce visitors. Subscriptions for the session and donations should be forwarded to the honorary treasurer, Mr. Arthur Evans, at 28, Devonshire-place, London, W.1.

THE DANGEROUS DRUGS ACT.—It is announced that from Sept. 1st the import and export of opium, medicinal opium, morphia, diamorphine (heroin), cocaine, and ecgonine are prohibited except under licence of the Secretary of State. Applications for licences to import any of these drugs should be addressed to the Under Secretary of State, Home Office, Whitehall, London, S.W.1, while applications for export licences should be addressed to the Board of Trade (Imports and Exports Department), Great George-street, London, S.W.1. The import and export of raw opium will only be allowed through the ports of London and Liverpool, and all packages for export which contain raw opium must be marked in a certain manner. The import, export, manufacture, sale, or possession of opium prepared for smoking is absolutely prohibited. Regulations for controlling the manufacture, sale, possession, and distribution in the United Kingdom of the above-mentioned drugs are being prepared and will be issued shortly. Pending the issue of these regulations the restrictions on dealings in opium and cocaine and on the manufacture of cocaine imposed by Defence of the Realm Regulation 40b will continue in force.

THE Joint Committee of the British Red Cross and St. John of Jerusalem have issued a leaflet setting out the needs and aims of the joint societies. They hope to collect £1,000,000 a year for the continued care of sick and wounded soldiers; for maternity, infant, and child welfare work; for the erection and maintenance of sanatoriums; the extension of the motor ambulance service and the peace library; materials for work parties for hospitals and welfare centres; and other benevolent purposes. "Our Day" is fixed for Thursday, Oct. 14th, when a special effort will be made to raise funds in commemoration of the amalgamation of the British Red Cross Society and the Order of St. John. During October and November effort will be made to collect funds for helping ex-soldiers and sailors still in need of treatment, for assisting the home civil hospitals and curative institutions, and for extension of the home ambulance service and peace library. It is hoped that the collections on one Sunday—Nov. 14th is suggested—throughout the kingdom will be donated to the joint societies, and an appeal to this effect has been signed by the Archbishops of Canterbury and York, Cardinal Bourne, and the heads of all the Free Churches. The amount from these Sunday collections will be shared with the Imperial War Relief Fund, which is dealing with the typhus scourge of Central Europe.

THE late Dr. David James Williams, of Llanelly, left £250 to the Llanelly Hospital for the better equipment of the operating theatre.

THE freehold of the Throat Hospital in Golden-square is being offered for sale with a view to the rebuilding of the hospital on a less costly site.

Dr. E. Roux, president of the Superior Council of Hygiene and director of the Pasteur Institute, has been awarded the Grand Cross of the Legion of Honour.

Mr. Robert Dunstan, M.R.C.S., L.R.C.P., barrister-at-law, has been appointed deputy coroner for the North-Eastern District of the County of London.

Dr. A. D. Cowburn, acting deputy coroner for North-East London, has been appointed deputy coroner for the South-Western district of London and the City of Westminster.

ON relinquishing his practice at Northwood on account of health, Dr. R. E. Humphry was the recipient of a presentation from his old patients. Dr. Humphry was surgeon in charge of No. 67 General Hospital at Salonika.

LITERARY INTELLIGENCE.—The *Clinical Journal*, founded in 1892 with the object of specially reporting and publishing clinical lectures given by leading physicians and surgeons of the day, has now resumed its weekly appearance. Messrs. H. K. Lewis and Co. are now responsible for publication and propose to include in it short notices of books likely to interest the general practitioner. The subscription price of the journal is 28s. 6d. a year, post free.

THE LATE DR. HENRY SHACKLETON. — Dr. Shackleton died at Sydenham, at the age of 73, on August 26th. Born at Moone, co. Kildare, in 1847, he only took up medicine comparatively late in life, and qualified M.D. Dub., M.R.C.S. Eng., and L.M.K.Q.C.P. Irel. in 1884. He practised at Sydenham for over 30 years, retiring about four years ago. Dr. Shackleton was the father of the distinguished explorer.

MEDICAL SICKNESS, ANNUITY, AND LIFE ASSURANCE SOCIETY, LTD.—The first general meeting of this society took place on August 23rd, three months after the conversion of the friendly society into a company. The chairman expressed regret at having to call a meeting of the members during the holiday season, but according to the memorandum of the company, it is necessary to hold a meeting at the end of three months after the incorporation. The conversion had been carried through quite smoothly. Only 21 members of the old society declined to become members of the company, and most of these were bordering on the age of 65, and therefore just about to sever their connexion with the society. Since conversion considerable progress had been made in all departments. The life assurance business had moved forward with a considerable boom, and in two and a half months proposals had been received for over £10,000. The sickness insurance had also considerably increased, proposals being received for 390 guineas. Dr. J. B. Ball, who acted as medical examiner for the society for a number of years, decided, on conversion, to resign his office owing to his advancing years. Dr. David Forsyth had been appointed as his successor. He was one of the original directors, but resigned on his appointment as medical examiner.

DOCTORS THREATENED AT CORK PRISON.—According to the *Belfast News Letter*, a threatening letter was received by the two medical officers sent by the Government to Cork prison for medical attendance on 11 prisoners hunger-striking there. The officers were Dr. C. J. MacCormack, a medical member of the General Prisons Board, and Dr. J. I. Kinsella, medical officer to the convict prison at Maryborough. The letter was signed C. Cork Brigade, I.R.A., and ran as follows:—

This is to notify you that we hold you responsible for the lives of the men at present on hunger-strike in Cork jail, and should any of them die there in jail, or after release, you will be guilty of death under the laws of the Republic. If you disclaim responsibility for the present treatment of these men, you can make this fact public by sending a notice of your resignation to the press to-night. This is the only action that will save you should a single prisoner under your charge die.

The Dublin Castle authorities gave it clearly to be understood that the two medical men went to Cork Prison under orders from the Government, and that as soon as they had examined the prisoners thus placed under their medical care they strongly recommended to the Government that on medical grounds the prisoners should be released. The statement concludes: "The responsibility of Dr. MacCormack and Dr. Kinsella is confined to taking such steps as are within their competence as medical men to relieve the condition to which the prisoners have been reduced by their own act."

RABIES IN WILTSHIRE.—In consequence of the occurrence of several cases of rabies in the neighbourhood a "dangerous" area has been proclaimed having a radius of about five miles round Salisbury and Wilton. A larger area with muzzling restrictions includes parts of Wilts, Hants, Dorset, and Berks.

SMALL-POX IN SCOTLAND.—474 cases of small-pox have been reported to date in the Glasgow district and the outbreak is becoming more evenly distributed throughout the city. Vaccination is stated to be falling off. Two cases were reported in Edinburgh last week-end.

CLOSING OF WHARNCLIFFE WAR HOSPITAL.—After more than five years' service as a military hospital under Lieutenant-Colonel W. J. N. Vincent, the South Yorkshire Asylum at Wadsley has been demobilised and reverts once more to its original duties as an asylum. One large block of buildings, however, remains a hospital for pensioners, and it is intended that all the sick pensioners in the district shall be treated there. This arrangement sets free the two wards at the Royal Hospital, which have for some months been used for pensioners in connexion with the Orthopaedic Fund Committee. A large number of men still receive medico-mechanical treatment at the Edgar Allen Institute, which, under the direction of Dr. R. G. Abercrombie, has proved of great value in this work during and since the war.

ROYAL HANTS COUNTY HOSPITAL, WINCHESTER.—A special appeal is being made throughout Hampshire on behalf of the County Hospital, Winchester, to obtain a sum of £6000 to pay off the overdraft due to the bankers. Sir Shadforth Watts has promised a contribution of £1000 provided the whole of the debt is paid off. The committee has resolved that the work of the hospital in future must be so conducted as to make the expenditure conform to the revenue. To carry out this policy one ward has been closed, and a scheme is being formulated with the assistance of the trade-unions whereby every wage-earner, man and woman, will be urged to contribute a small weekly sum to the hospital. In-patients are asked to contribute towards the cost of their food as far as their means permit.

Obituary.

PHILIP JOHN HENSLEY, M.D. CAMB. & DURH.,
F.R.C.P.,

CONSULTING PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL.

Dr. Hensley, who died at Shortheath, Farnham, on August 8th, was in his eighty-second year, and had lived long in retirement. He came up to London with a brilliant record from Christ's College, Cambridge, where he passed high as a wrangler. After qualifying M.B. Camb. in 1867 he early reached the position of house physician to St. Bartholomew's Hospital, and began to demonstrate physics in the medical school. He was a careful and minute observer, and an early contribution to the *Hospital Reports* was a mathematical demonstration of the exactitude of Sir William Roberts's yeast process for determining the amount of sugar in the urine. The same traits followed him into the out-patient department and the wards of the hospital, where his exact teaching was attractive to his clinical clerks. His lectures on forensic medicine contained sound substance and interesting detail, but were rendered unacceptable to students by an unfortunate defect of elocution. Hensley was no specialist in the narrow sense, but his knowledge of pulmonary diseases was such that cases from his clinic which led to an autopsy amply supported his diagnosis. At this time he was also physician to the Royal Hospital for Diseases of the Chest. Elected F.R.C.P. in 1871, Hensley was Goulstonian lecturer in the following year; he became Councillor in 1895, and Censor for the two years 1898-99. At the time of his death there were only five Fellows senior to him. In person Dr. Hensley was singularly modest and self-effacing, and of even temper. He married rather late in life a devoted wife, an accomplished painter in water-colours, and thus had to relinquish his Fellowship at Christ's College. He had no family, and his wife predeceased him. He retired from London after a full service at the hospital, taking with him the esteem of his colleagues, and much missed by all who understood his worth and appreciated his powerful intellect and sweetness of character.

Medical Diary.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Sept. 6th.—2 P.M., Dr. G. Stewart: Medical Out-patients. 2 P.M., Mr. D. Armour: Operations.

TUESDAY.—2 P.M., Dr. Burnford: Medical Out-patients. 2.30 P.M., Mr. Addison: Visit to Surgical Wards.

WEDNESDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Mr. Gibb: Eye Department.

THURSDAY.—2 P.M., Mr. D. Armour: Operations. 2 P.M., Mr. Sinclair: Orthopaedic Department.

FRIDAY.—10 A.M., Mr. D. Buxton: Dental Department. 2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear.

SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Dr. Owen: Medical Out-patients.

Daily.—10 A.M., Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

MALE LOCK HOSPITAL, Dean-street, W.

MONDAY, Sept. 6th, WEDNESDAY, AND FRIDAY.—5 P.M., Dr. C. Russ: Demonstration of the Treatment of Gonorrhoea by Electrolysis.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.

JOLL, CECIL A., M.S., M.B., B.Sc. Lond., has been appointed Surgeon to the Royal Free Hospital, and Consulting Surgeon to Royal Bucks Hospital, Aylesbury.

MULLALLY, G. T., M.C., M.S., F.R.C.S., Assistant Surgeon to the Westminster Hospital.

Certifying Surgeons under the Factory and Workshop Acts: **WALKER, A. (Cardenden)**; **WALLS, J. A., M.B., Ch.B. Glasg. (Bothwell)**; **GILES, A. C., M.B., Ch.B. Edin. (Sleaford)**; **BLAKE, V. H., M.B., B.S. Lond. (Great Yarmouth)**.

Vacancies.

For further information refer to the advertisement columns.

Barnsley, Beckett Hospital and Dispensary.—Sen. H.S. £250.

Battersea General Hospital (Incorporated), Battersea Park, S.W.—Third Res. M.O. £200.

Bedford County Hospital.—Asst. H.S. £150.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—Asst. P. 50 gs. Also Female H.S. £100.

Bengal, University of Dacca.—Chair of Physical Education. Rs. 9000 to Rs. 12,000.

Birmingham City, Salterley Grange Sanatorium for Consumptives.—Res. M.O. £550.

Birmingham General Hospital.—Surg. Registrar. £200.

Boole County Borough.—Tuberc. O. and Dep. M.O.H. £750.

Bradford Royal Infirmary.—H.S. £200.

British Guiana.—Asst. M.O.H. £600.

Bristol General Hospital.—Two H.P.'s, H.S., and Obstet. O. and H.S. £175 each.

Cancer Hospital, Fulham-road, S.W.—Asst. P. and Med. Reg. £250. Also Two H.S.'s. £150.

Cardiff, King Edward VII. Welsh National Memorial Association.—Asst. Tuberc. P.'s. £500.

Central London Throat and Ear Hospital, Gray's Inn-road, W.C.—Registrar.

Chester County Asylum.—Third Asst. M.O. £350.

Chester Royal Infirmary.—H.S. £200. Also H.P. £175.

City of London Hospital for Diseases of the Chest, Victoria Park, E.—H.P. £100.

Colonial Service.—M.O.'s for West African Medical Staff, Government Service in Malaya, East African Protectorates, West Indies (including British Guiana), Fiji, and the Western Pacific, &c.

Devonport, Royal Albert Hospital.—H.S. £200.

Durham County Council.—Female Asst. Welfare M.O. £600.

Durham University, College of Medicine, Newcastle-upon-Tyne.—Lecturer on Med. Jurisprudence.

East Africa.—M.O. to C.M.S., Kavirondo.

Edinburgh Royal Infirmary.—Asst. Path., Asst. Clin. Path. £500 each. Also Second Asst. Clin. Path. £350.

Exeter, Royal Devon and Exeter Hospital.—Surg. Reg. Asst. M.O. in Electrical Treatment Dept.

Great Northern Central Hospital, Holloway-road, N.—H.P. £150.

Huddersfield Royal Infirmary.—Asst. H.S. £150.

Hull and Sculcoates Dispensary.—M.O. £500.

Hull Royal Infirmary.—Asst. H.S. £150.

Ingham Infirmary and South Shields and Westoe Dispensary.—Jun. H.S. £175.

Kensington Board of Guardians.—Fourth Asst. M.O. £250.

Kent Education Committee.—Sch. Med. Inspec. £562.

Liverpool Dispensaries.—S. £300.

London Lock Hospital, Soho, W.—Hon. S.

London Temperance Hospital, Hampstead-road, N.W.—H.P. £120.

Maidstone, Kent County Mental Hospital.—Jun. Asst. M.O. £300.

Manchester, Ancoats Hospital.—Anæsth. 10s. 6d. per attendance. Also Res. Surg. O. £250.

Manchester Royal Eye Hospital.—H.S. £120.

Manchester Royal Infirmary, Barnes Convalescent Hospital, Cheadle.—Res. M.O. £300.

Manchester Royal Infirmary, Central Branch, Roby-street.—Res. M.O. £250.

Manchester and Salford Hospital for Skin Diseases.—H.S. £100.

Margate, Royal Sea Bathing Hospital.—Res. S. £200.

M.A.B., Colindale Hospital, Hendon, N.W.—Sen. Asst. M.O. £645 5s.

Also Jun. Asst. M.O. £515 6s.

Metropolitan Hospital, Kingsland-road, E.—Cas. O. and Res. Anæsth. £120. Also Asst. H.S. and Asst. H.P. £100 each.

Middlesex County Council, Harefield Sanatorium.—Res. Med. Supt. £700.

Ministry of Health.—Asst. Bacteriologist. £300.

Ministry of Health, Welsh Board of Health.—M.O.'s. £600.

National Hospital for the Paralyzed and Epileptic, Queen-square, Bloomsbury, W.C.—Registrar. £200. Also Sen. H.P. £150.

Newport, Mon., Education Committee.—Female Asst. Sch. M.O. and Med. Inspec. of Sch. £500.

Nottingham.—Asst. to City Pathologist. £500.

Preston and County of Lancaster Royal Infirmary.—H.S. and H.P. £180 each.

Reading, Royal Berkshire Hospital.—H.P. and Second H.S. £200 each.

Royal Chest Hospital, City-road, E.C.—Asst. M.O. £450.

Scarborough Hospital and Dispensary.—Two H.S.'s. £150.

Scottish Board of Health.—Dist. M.O.'s. £1000.

Sheffield Royal Hospital.—Asst. Cas. O. £150.

Sheffield Royal Infirmary.—H.P. and H.S. for Ear, Nose and Throat £150 each.

Sheffield University, Department of Pathology and Bacteriology.—Director. £800. Asst. Director. £500. Curator of Path. Museum. £600.

South London Hospital for Women, South Side, Clapham Common, S.W.—Female Asst. S. Also Clin. Assts.

Stafford, Staffordshire General Infirmary.—H.P. £200.

St. Mary's Hospital, Paddington, W.—Med. Supt. £350.

Sudan Medical Department.—M.O. £840.

Sunderland Royal Infirmary.—Jun. H.S. £200.

Taunton and Somerset Hospital.—Jun. H.S. £150.

Uganda.—M.O. to C.M.S. Mengo Medical School.

Union Mental Hospital Service, South Africa.—Jun. Asst. P.'s. £400.

University of London.—Prof. of Med. and Director of Med. Clin. £2000.

Ventnor, Isle of Wight, Royal National Hospital for Consumption and Diseases of the Chest.—Asst. Res. M.O. £300.

Westmorland Sanatorium and Home, Meathop, Grange-over-Sands.—Res. Asst. M.O. to the Westmorland Sanatorium and Asst. Tuberc. O. for Westmorland. £350.

Wolverhampton and Staffordshire General Hospital.—Res. M.O. £200.

The Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Strabane, Dingwall (Ross), and Poole (Dorset).

Births, Marriages, and Deaths.

BIRTHS.

DRESING.—On August 26th, the wife of Captain H. G. Dresing, M.C., R.A.M.C., of a son.

HARTRIDGE.—On August 24th, at Millington Lodge, Millington-road, Cambridge, to Dr. and Mrs. Hartridge—a son.

NICKERSON.—On August 22nd, at a nursing home, Salisbury, the wife of Colonel W. H. S. Nickerson, V.C., C.B., C.M.G., R.A.M.C., of a daughter.

SMITH.—On August 18th, at Larkhall-rise, Clapham, S.W., the wife of Alex. A. Smith, L.D.S. Eng. of a son.

SPARROW.—On August 29th, at Wayside, Watford, the wife of E. C. Sparrow, M.A., M.B., B.C., of a daughter.

WARREN.—On August 10th, the wife of Surgeon Commander L. Warren, O.B.E., R.N., of a daughter.

MARRIAGES.

DAY—HUGHES.—On August 26th, at St. Clement's Church, Sandwich, Kent, by the Rev. O. Bruce Payne, Vicar, assisted by the Rev. B. W. Day, father of the bridegroom, Harold B. Day, M.C., M.D., F.R.C.P., of Cairo, Egypt, to Winifred Blanche West, second daughter of Mr. and Mrs. W. J. Hughes, of Strand House, Sandwich.

GORDON-TAYLOR—PEGRUME.—On July 24th, at All Souls, Langham-place, Gordon Gordon-Taylor, O.B.E., M.A. Aberd., M.S., M.B., B.Sc. Lond., F.R.C.S., to Florence Mary, eldest daughter of John Pegrume, of Waltham Abbey, Essex.

HORT—THOMPSON.—On August 17th, at Distington Parish Church, Cumberland, Frederick Aylmer Hort, M.A., M.D., B.Sc., L.R.C.P., M.R.C.S., to Muriel Mary, eldest daughter of the Rev. George and Mrs. Thompson.

MAHONY—BURNS.—On August 25th, at the Church of the Holy Name, Manchester, by the Rev. B. Butler, S.J., Martin James Mahony, L.R.C.P. & S. Edin., L.R.F.P.S. Glasg., to Elizabeth, daughter of Mr. and Mrs. Thomas Burns, Rochdale.

MEARNS—GOODRICH.—On August 18th, at All Saints Church, Child's Hill, Captain Alexander Mearns, R.A.M.C., to Gladys Audrey, elder daughter of Mr. and Mrs. Cavendish Goodrich, Ilfracombe.

DEATHS.

HUNT.—On August 26th, at Chagford, Albert W. Dunning Hunt, M.R.C.S., L.R.C.P. Lond., in his 45th year.

SHACKLETON.—On August 26th, at Longton-grove, Sydenham, Henry Shackleton, M.D., Trin. Coll. Dublin, in his 74th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

SEXUAL MATURITY AND SENILITY: RECENT EXPERIMENTAL STUDY.

SENILITY, according to Dr. E. Steinach—sometime professor of physiology in the German University at Prague and now in Vienna—is occasioned through lack of the hormone secreted by Leydig's cells. His book, "Verjüngung," recently published by Julius Springer in Berlin, describes the various steps which have led to successful rejuvenation. Marshall and Jolly originated this research in 1908, when they showed that a transplanted ovary is capable of maintaining the sexual characters of the individual. About the same date, Steinach observed that autoplasmic transplantation of the testes in a juvenile rat produced normal development of the vesiculæ seminales, prostate, and penis, but that the hormone concerned arose, not from the generative cells, but from the interstitial cells described by Leydig. These experiments disposed of the theory that the effect of the testes is to be explained by Ehrlich's side-chain theory. In the female rat, as well as in the male, sexual characters are found to be dependent on the interstitial cell hormone. Experimenting with castrated infantile rats, Steinach observed that the transplantation of normal testes brought about reproduction of the interstitial cells, but degeneration of the spermatocytes. The animal thus treated also displayed an accentuated libido and potency, together with a hyperdevelopment of the secondary sexual characters. The intimate relation between the interstitial cells and sexual development was further emphasised by the fact that such development could be controlled by the operative addition or removal of grafted tissue. The conclusions drawn from the histological sections will require confirmation for, as B. Romeis has pointed out in the current number (August 27th) of the *Munch. med. Wochenschr.*, the staining method employed by Steiner was not adapted clearly to distinguish between interstitial fibrosis and interstitial glandular hyperplasia.

Rejuvenation of Senile Rats.

Owing to the close resemblance between the undeveloped condition of the secondary sexual characters in the animal whose hormone-producing tissue had been artificially reduced, and the condition in the senile animal, Steinach was led to believe that the latter also could be brought under control. He therefore endeavoured to restore vigour and potency to senile rats in the same way as he had restored them to castrated juvenile individuals. He selected rats for the purpose of these experiments as they rapidly develop senile symptoms—the average lifetime being two years—and also the difference in appearance and behaviour between young and old individuals is so marked that any alteration is easily discernible. Steinach claims almost invariable success as a result of his operative methods, which consisted of ligature of the vas deferens or coni vasculosi between the testes and epididymis. Rats that had previously shown every symptom of senility, such as total loss of potency and sexual interest, inactivity, lousy condition, baldness, &c., within two weeks were completely rejuvenated. They became active and clean; the hair reappeared; the media of the eye regained their youthful transparency. Sexual interest and potency were restored, frequently to a hypernormal degree. A brief summary of his notes on one of the experiments will bring out these points more forcibly:—

Male rat, aged 27 months; no sexual potency and every sign of senility: operated on 2/3/14. Ligature of coni vasculosi between testes and epididymis on both sides. Hypernormal sexual activity and potency 20/3/14. Gain in weight and appetite: very active, inquisitive, and courageous 30/3/14.

In the case of females, by transplanting the ovaries of a four months' old individual into a senile individual of the same sex, he produced a complete change in the appearance of the subject. The degenerated mammary glands reappeared, and the animals gave birth to healthy offspring.

Application to Man.

Steinach was so encouraged by the success of his experiments on rats that he determined to apply the same methods to men. For advanced cases of male senility he recommends a simple ligature of the vas deferens, while in the case of those suffering from premature senility he has obtained results that were very satisfactory by ligature of the coni vasculosi. These operations have been performed by Dr. Lichtenstern, under the direction of Steinach. Several cases are described in Steinach's book, but it will be sufficient to quote one here.

A man, 71 years old, suffering from breathlessness, trembling, weakness of the heart, feeble mentality, and impotence was obliged to have his left testicle removed on account of an abscess.

At the same time the ligature of the vas deferens to the right testicle was carried out. Within a few months after the operation the man was muscularly and organically strong. He grew fresh hair and beard, and his face assumed a youthful appearance. Sexual interest and potency were restored to a marked degree.

In passing it may be remarked that no such rejuvenation has been recorded in this country in the many cases in which the vasa have been tied in old men for prostatic hypertrophy. The operator in fact rather had in view the abolition of sexual vigour. Although in the case of female rats Steinach produced rejuvenescence through the transplantation of the ovaries of a young individual, this method has not as yet been applied to women owing to lack of opportunity. Steinach believes that it would prove successful if tried. Further research into the rejuvenescence of women will, he thinks, develop the use of X rays, which have been successfully employed to stimulate the reproduction of the interstitial cells in animals.

Experimental Masculinisation and Feminisation.

There is ample experimental and other evidence to show that in the vertebrata the internal secretions of the generative glands are factors and perhaps the chief factors in determining the development of the visible secondary sexual characters, and that the factors act independently of the normal generative functions of the glands. The source of the internal secretion or secretions of the ovary is not so definitely proved to lie in the interstitial cells as is that of the testis. The effects of removal of both organs are well known, and so are some of the effects of grafting of these organs. Steinach, however, between 1911-13 added considerably to our knowledge by his experiments on the transformation of the sexual characters in mammals by exchanging the sexual glands. Homologous transplantations are conducted between individuals of the same sex and heterologous between individuals of different sex—so-called "experiments on transformation." Steinach showed—and this has been confirmed by other observers—that preliminary castration of the experimental animal is absolutely essential for the ingrafting of the heterologous gonads, for if there be no previous castration the graft perishes. Whether this is due to an antagonism between the sexual hormones as maintained by Steinach or to an immunity of the non-castrated organism from the hormones of the heterologous sexual organs as more recently suggested by K. Sand need not here be discussed, but the striking physical and psychical effects resulting from the grafts are remarkable. Steinach castrated young guinea-pigs and rats, and grafted at the same time ovaries from the same species, either under the peritoneum "in pockets" or subcutaneously. The grafts took root, healed, grew, and became fully functional in the body of the male; the primordial follicles developed to large follicles with normal ova and some reached maturity, burst, and formed corpora lutea with typical lutein cells. The interstitial cells of the ovary also showed a tendency to increase. The implant had all the essential characters of a functional ovary, though it did not attain the same size as in the normal animal. The graft had no accelerating influence on the growth of the true male characteristics—the penis, prostate, and vesiculæ seminales remained infantile just as they do in early castrated males. If, however, the uterus and Fallopian tube were ingrafted with the ovary they were stimulated to growth and development. Specially noteworthy were the effects on the mammary gland—nipple, areola, and glandular tissue—their growth was greatly accelerated and this became as large as the corresponding parts in a normal female of eight to ten months. The influence of the transplanted ovary also affected the growth, proportions, and form of the body and skeleton, and the animal assumed the general characters of a female. Even the hair and fatty deposits corresponded to the female type.

The most prominent change, however, was that of the psychical sexual characters. The animals did not behave with indifference towards normal males as do castrated males, but showed marked sexual instincts and were treated as females. The necessary hormones, probably derived from the thecal tissue and corpus luteum, produced typical female somatic and psychical changes in the male—i.e., what has been called "feminisation." Similarly by grafting testes on castrated young guinea-pigs or rats—i.e., heterologous transplantations—"masculinisation" may be produced. The clitoris in the rat becomes greatly hypertrophied. Lipschütz described in one of Steinach's masculinised guinea-pigs hypertrophy of the clitoris, two corpora cavernosa, and also the quill-shaped growths of the male, so that this penis-like organ represented a totally hypospadiacal penis.

Production of Animal Hermaphrodites.

In 1916 Steinach by ingrafting at the same time both kinds of sexual glands on the same infantile castrated male succeeded in producing a hermaphrodite animal. The experimental animal showed a development of homologous and heterologous characters, both somatic and psychical,

and, what is more remarkable, the psychic characters became periodically either male or female. K. Sand has more recently confirmed these observations and improved the technique. A testis and an ovary may be simultaneously transplanted into an infantile mammal. The ovary may even be placed in the middle of the grafted testis, forming an ovario-testis when the ovary grows and forms corpora lutea and the testis flourishes. It is thus possible to produce an artificial hermaphrodite both somatically and psychically. These remarkable results may be commended to the consideration of those who have read the attractive lecture by Sir F. W. Mott on "Body and Mind," published in THE LANCET of August 21st, 1920, in which he discusses the Freudian school of psychologists who "assert that all psychic energy has its roots in sexual instinct, and maintain that the sexual life of the individual begins its development at birth or even before birth."

SANITARY CONDITION OF THEATRES AND MUSIC-HALLS.

THE unsatisfactory sanitary conditions in those parts of theatres and music-halls to which the public are not admitted have long been the subject of legitimate complaint by artists and staff. Not only is there want of proper lavatory accommodation, insufficient ventilation, and dirt in dressing-rooms, but the complaints received by the Ministry of Health have included instances of defective structural conditions and inadequate precautions against fire. The sanitary conditions in many theatres and music-halls are represented as so unsatisfactory as to endanger the health of persons employed in the performances. The Ministry has issued a circular to local authorities, suggesting that all theatres, music-halls, and other places of public entertainment should be visited periodically by inspectors of nuisances, who should report both to their authority and to the licensing authority any cases in which the conditions are found to be unsatisfactory. The co-operation of the Secretary of State has been enlisted and licensing authorities are being asked to require a certificate from the inspector of nuisances that the condition of the building is satisfactory in sanitary and other respects before the granting or renewal of a licence. This combined action should lead to a prompt amelioration of conditions which have long been a reproach to the business side of drama.

BROUGHT TO THE BOIL.

THE following incident, which happened at the Great Northern Central Hospital, is given in the first number of *Progress* (price 3d.) as an instance of the need for hygienic education in the neighbourhood served by the hospital:—

A young mother recently brought her baby to the hospital, and the medical officer on examination found that the child was suffering from convulsions. He prescribed the necessary treatment, and the mother inquired as to what procedure she should adopt in the event of the child suffering from a similar attack. The doctor advised her to put the baby into a bath of warm water. A few weeks later the mother again brought her child to the hospital, and the doctor, on a further examination, discovered signs of the infant having been burned. He inquired of the parent the cause of the injury, when she stated that upon the child receiving a further attack, and she not having any warm water available at the moment, placed the baby in a bath of cold water, which she placed upon the fire in order to bring the water to the necessary temperature.

The hospital is enrolling a corps of collectors and using this little journal as a method of propaganda.

THE CORROSIVE CONTENTS OF A GOLF-BALL.

AN inquest was held at Blackburn on August 19th on a young girl who had picked up a golf-ball, and who died after swallowing some liquid which she had obtained when stripping off its coverings with her teeth. The analysis showed that the core of the golf-ball was a liquid contained in a small rubber pouch with a tubular opening tied with a piece of rubber tape. Most of the liquid had leaked out, but what remained was strongly alkaline in reaction and its basic principle was silicate of soda. A jelly-like mixture of the same appeared to form the core of the ball, and in biting the covering the girl probably swallowed some of the corrosive contents, which caused acute alimentary inflammation, ulceration, and subsequent death.

IN THE LANCET of July 18th, 1914, we recorded the case of serious injury done to the eye of a golfer through the inner core bursting on his making an inquisitive examination of the construction of the ball. A companion ball at the time was examined in THE LANCET Laboratory, and the inner rubber pouch was found to contain a fluid of high density, which proved on analysis to be a strongly alkaline fluid, consisting mainly of potash soap. We concluded our note by the following sentence: "For the sake of children who may get possession of old golf balls we think that it should be widely known that to experiment with the structure of certain varieties is attended with grave risks." The incident recorded is a regrettable case in point.

DISCONCERTING ACCURACY.

A MEDICAL man examining a new deaf patient asked as a preliminary question, "Is it your right or your left ear that is troubling you?" and received as a reply, "It is my middle ear."

THE LITERARY YEAR BOOK.

To the Editor of THE LANCET.

SIR,—It is intended to make this work an absolutely reliable reference book. Would you kindly permit me, therefore, through your columns, to request authors who have not hitherto sent to the editor of this book details of their works to do so as soon as possible? In all cases a proof will be sent for personal correction, and it is requested that communications should reach me before Sept. 30th.

I am, Sir, yours faithfully,

MARK MEREDITH,

67, Dale-street, Liverpool, August 17th, 1920.

Editor.

Communications, Letters, &c., to the Editor have been received from—

The Lumleian Lectures

ON THE

CLINICAL EXPERIENCES OF A PHYSICIAN DURING THE CAMPAIGN IN FRANCE AND FLANDERS, 1914-19.

Delivered before the Royal College of Physicians of London

By SIR JOHN ROSE BRADFORD, K.C.M.G.,
C.B., M.D., F.R.S., F.R.C.P.

LECTURE I.

MR. PRESIDENT, FELLOWS OF THE COLLEGE, AND GENTLEMEN,—My first duty is to express to you, Mr. President, and to the College my sincere thanks for the honour conferred on me by the request to deliver these lectures to the College. In seeking for a subject suitable to the occasion it seemed that a short description of some of the clinical manifestations of disease such as I had the opportunity of observing whilst acting as a consulting physician to the British Expeditionary Force might be of interest. Such an account, however, as given now, must be very incomplete, and will, in fact, consist of little more than a record of some impressions, a survey of a more or less cursory character of the observation of very large numbers of cases of diseases of very different and varied nature. Further, it will deal more especially with disease from the standpoint of general medicine rather than with the special diseases directly related to the operations of war itself, such as trench fever and the effects of gas warfare.

VARIED OPPORTUNITIES FOR CLINICAL STUDY.

I propose, however, to discuss in one lecture some of the clinical phenomena seen as a result of gunshot wounds of the chest, the study of which revealed many interesting features. The field available for clinical study was enormous; the mere numbers concentrated in the larger hospital areas, where it was not unusual for some 20,000 or more beds to be occupied, alone afforded opportunities never, perhaps, available before. This mass of clinical material, thanks to the organisation of the Medical Services, the large number of skilled medical officers, and the equipment of the military hospitals, could be studied in a satisfactory manner, although naturally the exigencies of military service prevented in some instances the complete study of cases interesting only from the standpoint of medicine.

The field available for observation was not only large but also varied. In the earliest periods of the war the army consisted of a specially selected portion of the male population, inured to military service. Later, but still early in the war, the armies were formed of the finest specimens of the youth of this country, who, after undergoing a prolonged training, came out to France in magnificent health and in full vigour of body and mind. Later the periods of training were necessarily shortened, the age of the men increased, the standards somewhat relaxed, and towards the end of the war a certain proportion of the men were considerably younger and the standard of physique lower. These differences, however, were not those that made the opportunity of the physician so unique; this arose rather from the variety of race represented in the forces. From an early period of the war we had large numbers of soldiers from the Dominions—Canadians, Australians, New Zealanders—and a very short clinical experience often showed that these men reacted to disease in a manner different from that seen with our own home troops. Further, the Indian troops and those from the West Indies also afforded much food for thought, not so much from the point of view of the introduction of diseases more or less peculiar to or prevalent in these races, but rather from the point of view of the extraordinary differences in their reaction to the diseases prevalent in France

No. 5063

and Flanders and affecting Europeans and those of European descent.

Thus the material available for clinical study provided by the actual fighting men was extraordinarily large and varied, but the field was really much greater than this, because in the latter stages of the conflict large numbers of men were enlisted for labour companies, and an army of women was also enrolled, in addition to the large number of women who had been engaged in nursing from the earliest stages of the war. When all these organisations were in full working order, as they were during the latter half of the war, the population that fed the hospitals was comparable to that of civil life, but with the very important qualification that it was still a selected population, both as regards age and as regards physique. The physician had the opportunity of studying the incidence of disease in a population where all diseases were, so to say, "notified," and not, as in civil life, where only certain diseases are so notified. This fact alone should provide ultimately much material of value for the study of disease, but naturally this subject is much too large to be dealt with here, and can only be adequately considered in the medical history of the war. Further, the experience of one individual, large as it was, is necessarily far too limited to deal with such an enormous and varied mass of material.

Although disease in war has usually claimed more victims than direct enemy action, and although military operations have often been hampered by the outbreak of disease, and especially of epidemic disease, yet the Great War was the only one in recent times where the military authorities made any special provision for physicians to accompany the armies in the field. Although from time to time in the past certain army medical officers in the field devoted themselves more especially to the problems connected with the sick, nevertheless the rôle of the doctor in the field was held to be that of an officer dealing especially with battle casualties. This is very natural when one considers the urgent nature of the medical, the military, and the humanitarian problem that presents itself during an engagement, whether it be part of an advance and attack, or the still more difficult question of dealing with the wounded when the military operations demand a retirement. The problem the military surgeon has to solve to the best of his ability is an urgent one, brooking no delay; the need is obvious and patent to all, even to those most ignorant of medicine. Failure to deal successfully with the wounded, either from the professional or the administrative side, is so obvious to all that it is not surprising that this side of the army medical officer's work has loomed large in the eye of the army, the medical profession, and the public, and it is right that it should do so, as it is work of the greatest importance from all points of view—military, professional, and humanitarian.

The rôle of the physician is different, but none the less also of value, both from the professional and military points of view. It is often said that his main function is the prevention of disease, although some would place prevention under the sole control of the sanitarian (who may or may not be a physician), and would seem to be under the impression that surgery and sanitation between them included all the problems likely to be met with by an army during military operations. Great as are the services rendered by the sanitarian, especially with an army in the field, the physician is still required, inasmuch as the prevention of the spread of disease requires not only the recognition or diagnosis of fully declared and typical instances of disease, but also the recognition of anomalous forms of common diseases. This is often a matter of some difficulty and one requiring considerable clinical experience and acumen and one of peculiar importance in military medicine, where the prevention of epidemic disease may well depend on the recognition of initial cases perhaps anomalous in their clinical manifestations. With this aid all the resources of the sanitarian can be brought to bear on the problem at once and early. The surgeon, the sanitarian, the bacteriologist, and the physician are all required in order to

deal adequately with medical problems on active service, and, further, they must work together and in harmony; no one of them can take on and perform satisfactorily the duties of the other; still less can any one of them deal with the whole problem. This was recognised only to some extent in the Army Medical Service prior to the war, encouragement was given to medical officers to specialise as surgeons, sanitarians, or bacteriologists, but it took several years of war for the real value of clinical medicine, as a subject of considerable importance for the maintenance of the efficiency of the fighting machine, to be recognised. Then steps were taken to place officers with special qualifications for the work in positions where their work could be effective.

The Surgical and the Medical Side.

The work of the army surgeon and of the army physician is in many respects very similar, and has the same general objects in view. Thus there is the humanitarian side, which concerns itself with attempting to provide the best possible treatment to the wounded and to the sick. Then there is the military side, which is more especially the problem of "wastage" and the best methods to adopt to check wastage and to bring the sick or wounded man back to duty as soon as possible. This question is of the first importance, both on the surgical and on the medical side, but it is a much bigger and more difficult question on the medical side, and it is here that the physician is of most value to the efficiency of the military machine. Surgery in the late war has done much to check undue wastage owing to the improvements effected in the treatment of wounds and the shortened stay of the wounded in hospital. This work was especially valuable inasmuch as wounded men, apart from their wounds, were in robust health, and thus provided the wound was soundly treated, could return to duty in a comparatively short time, especially in the case of the more slightly wounded. On the medical side the control of wastage was more difficult for several reasons. In the first place, the numbers dealt with were far larger, although this war, at any rate so far as concerns the campaign in France and Flanders, has been remarkable for the relatively small amount of disease, still the actual numbers of sick have been far larger than the number of wounded. Further, it must be remembered that the casualties from gas warfare were treated by physicians, although for statistical and other reasons they were included amongst the battle casualties and regarded as wounded.

Wastage.

These cases afforded many problems in connexion with the question of wastage, problems by no means simple in nature and requiring for their solution all the skill and experience of trained medical observers. Thus it may be said that not only was the number of cases very large on the medical side, but also that the question whether a man was fit to return to duty was very often a difficult one requiring much clinical experience for its solution. Wastage, however, arises quite apart from battle casualties, whether from wounds or the effects of gas warfare, or from nervous disorders, and in fact in all wars, including the late war, the main wastage is dependent upon disease and often on disease that might at first sight be thought of little interest or importance. Here the work of the physician is of especial value, as an extraordinary amount of wastage may ensue as a result of erroneous or incomplete diagnosis; disease of the skin and functional disorders of the heart afford illustrations of such conditions. Wastage on a very large scale may ensue as the result of the spread of epidemic disease. In some instances as, for example, in the outbreaks of true influenza in 1918, our present available methods of dealing with such problems only yield a very moderate measure of success. In other cases, such as the formidable diseases, cerebro-spinal fever and dysentery, much greater success is achieved, but in all cases success is largely dependent upon the recognition of early cases. The records of medicine, civil and military, old and recent, contain numberless instances of epidemics of disease where

the initial cases were diagnosed erroneously. On the other hand, they also record instances where an acute clinical observer has recognised a malady in an unusual form, and prompt measures have led to the suppression of the threatened outbreak. In an army such questions are of the very first importance; much harm may result from initial cases of dysentery being regarded as diarrhoea, or of cerebro-spinal fever being thought to be that protean disorder, influenza. These are questions of clinical medicine, although for their complete solution the services of the bacteriologist are required. Much harm, however, may be done by placing undue emphasis on one or other of these two branches of knowledge, especially in an army in the field. Thus some would take the view that no diagnosis of dysentery is justified unless there is bacteriological proof of the presence in the excreta of the causative organism. This is, of course, the correct attitude to take in a contribution to the study of the disease, but it is not the correct view to take when dealing with a supposed outbreak of the disease in an army in the field. There the opinion of the clinician, formed summarily at the bedside and based on symptoms, should be sufficient for the case to be regarded and treated as dysentery, at any rate temporarily, pending further and more complete study. Doubtless, errors will be made, and some cases not dysenteric in nature will be regarded as such, but much less harm will be done than by refusing to regard a case as dysenteric until the organism has been isolated. Much dysentery, especially in armies, will always be regarded as mere diarrhoea, but all cases with blood and slime in the motions should unhesitatingly be labelled dysentery on clinical grounds alone. Epidemics of dysentery in armies are prone to develop considerably before being adequately and firmly treated, owing to the tendency to regard the early cases as mere diarrhoea, for a variety of reasons. Much may be done to minimise this danger if care is taken to segregate, whenever possible, cases of diarrhoea.

The control of wastage from dysentery is mainly a question of diagnosis and sanitation, but here, as in the cases of enteric fever and cerebro-spinal fever, there is also the vexed and very difficult question of "carriers"; and the frequency of relapse as a result of a return to normal food still further complicates the problem of wastage in the case of dysentery. All these questions demand for their solution much clinical experience, but a great deal can be done to check this wastage by accurate clinical diagnosis.

I propose, Sir, after these general introductory remarks, to pass on to the consideration of certain experiences that are not without interest. In one lecture, the third, I propose to deal with some of the clinical phenomena seen as a result of gunshot wounds of the chest; in my second lecture I hope to discuss certain diseases, such as nephritis and polyneuritis, from the clinical side; and, to-day, to deal more generally with certain impressions formed as a result of the survey of the clinical field as a whole and from the standpoint of general medicine rather than from that of the special pathological states induced as a direct result of active service.

ORGANIC HEART DISEASE.

In the first place, it may be said that, speaking broadly, the medical examinations made in this country prior to the men being sent overseas were successful in detecting gross organic disease, even in its many latent forms. This is shown by the fact that it was exceptional to meet with patients suffering from obvious organic diseases, such as diseases of the heart, although, as might be expected, a few cases of aortic regurgitation that had escaped detection were seen from time to time, and amongst the large numbers of cases of paroxysmal tachycardia that came under observation a few cases of mitral stenosis and some with auricular fibrillation were met with. One such case of auricular fibrillation was of considerable clinical interest, in that it illustrated a rare type with a group of symptoms only occasionally

seen, and these very liable to lead to difficulties in diagnosis owing to the simulation of an acute abdominal condition. The attacks of paroxysmal tachycardia seen in cases of auricular fibrillation may not only sometimes be very sudden in their onset, but may also be ushered in with severe abdominal pain instead of mere præcordial discomfort. This abdominal pain may be epigastric in position and accompanied with some local tenderness, together with some nausea and vomiting. The patient may be apparently very ill, with considerable collapse and much anxiety. In such a case an error of diagnosis may easily be made, if attention is concentrated on the abdominal pain and vomiting. The characteristic irregularity of the pulse may not be correctly interpreted, and the case may be regarded as an abdominal one and a perforation of the stomach or intestine diagnosed, the pulse being attributed to the effects of collapse, whereas in reality it is characteristic of the cardiac lesion present. I have seen two such cases—one, the case alluded to above, and one in civil practice prior to the war. In both laparotomy was performed under the mistaken diagnosis of perforation owing to the marked character of the abdominal symptoms and the apparent alarming condition of the patient; although in reality auricular fibrillation in association with mitral stenosis was the sole lesion present. In both cases the patient recovered. Mitral stenosis is not the only chest condition in which this error may be made; somewhat similar epigastric pain, together with collapse and some vomiting, closely simulating an acute abdominal lesion, may be seen, as is well known, in certain cases of angina pectoris, and also, strange as it may seem, in cases of sudden and extensive pulmonary embolism. In the latter instance the presence of urgent dyspnoea and of some degree of cyanosis should, however, be sufficient to prevent such an error of diagnosis.

RARITY OF CASES OF ACUTE RHEUMATISM.

Valvular disease of the heart was then an uncommon lesion, and this leads naturally to the consideration of one of the most interesting features of the medicine of the war—i.e., the rarity of the occurrence of acute rheumatism. Very few cases of this malady were seen, although such as did occur were of the classical type, and not uncommonly accompanied with pericarditis with effusion. When we consider that we were dealing with a population of an age suitable for this malady, and what the conditions were as regards exposure to cold, damp, and wet, to say nothing of fatigue, it is certainly noteworthy that the disease was as exceptional in its incidence as it proved to be. This fact would tend to support the views of those who hold that this disease is not specially associated with exposure to wet and damp. Further, it would seem that this experience in the recent war is similar to that recorded for the British Army in the Crimean campaign, where, notwithstanding the rigours of the climate, pericarditis of rheumatic origin was uncommon. The experience as to the incidence of acute rheumatism in this war is more especially interesting owing to the fact that this malady was equally uncommon amongst the large numbers of women employed by the army, although they also were of an age favourable to its occurrence. The very different incidence of acute rheumatism in the military hospitals in France from that familiar to us in civil hospitals in London was therefore very striking.

One case of acute rheumatism in a young nurse merits notice owing to the anomalous mode of onset and unusual clinical course of the malady. A nurse whilst on duty and not obviously ill was seized with symptoms of præcordial discomfort and slight faintness, and was found on examination to have slight pyrexia, the temperature being a little over 99° F. and a very slow pulse, both the pulse-rate and that of the heart being only 30 per minute. She was confined to bed, and the bradycardia and slight pyrexia persisted without the development of any other signs or symptoms beyond a faint systolic apical murmur that was not always audible. The pulse-rate gradually returned to the normal rate, and at the end of a week the temperature rose to between 101° and 102° F. and effusion occurred into many joints, the ankles, wrists, knees, and elbows, together with much pain, and the illness then followed the normal course of an attack of acute rheumatism, and the systolic

apical murmur that had been heard occasionally and with difficulty in the earlier stages became now quite marked and obvious. The pulse increased considerably in rate, and the cardiac features of the case became much more pronounced in that there were considerable palpitation and tachycardia and the heart became enlarged, although there was never any evidence of pericarditis. On two separate occasions attacks of very severe tachycardia occurred, accompanied with extreme irregularity of the rhythm, and the pulse could not be counted owing to its frequency. These attacks were very severe and lasted several hours, and on one occasion the patient was in a critical condition for several hours. Recovery took place very slowly, and the patient was confined to bed for several months. Ultimately she recovered sufficiently to return to this country and some two years after the illness she was in good health, vigorous and able to return to work, presenting no abnormal physical signs except a faint apical systolic murmur with no signs of appreciable cardiac enlargement.

This patient would seem to have been an instance of one of those rare cases where the rheumatic virus affected primarily the myocardium, causing first bradycardia and subsequently extreme tachycardia probably due to auricular fibrillation, but certainly due to pathological changes in the auricular muscle. During the whole of my service in France no case of death from acute rheumatism came under my notice, nor did I see any case of rheumatic hyperpyrexia.

INFECTIVE ENDOCARDITIS.

A certain number of cases of infective or malignant endocarditis were, however, seen, although there were no reasons on clinical grounds for associating them with acute rheumatism; these cases presented both clinically and on post-mortem examination some features of interest. In view of the enormous number of septic wounds, especially during the first years of the war, it might have been expected on a priori grounds that infective endocarditis would have been of very frequent occurrence. The physician was not uncommonly asked to see cases where this complication of an infected wound was suspected to be present, owing to the presence of persistent and irregular pyrexia and the absence of any obvious cause for this in the state of the wound itself. It was, however, rare for signs to be present sufficient to justify such a diagnosis inasmuch as these cases usually presented only an irregular temperature and possibly a systolic murmur, signs, it is true, of a septic infection, but not characteristic of or limited to infective endocarditis. Post-mortem examination of large numbers of such cases showed the rarity of acute infective endocarditis as an early complication of infected wounds. Careful observation by a number of surgeons showed, on the other hand, that many of these cases were really of a different nature and dependent upon the wound infection causing thrombosis of, or even the presence of purulent clots in, the great veins of a limb, stump, or other part.

Whilst acute infective endocarditis was only rarely seen as a complication of septic gunshot wounds, quite a number of cases were seen where it arose primarily and in unwounded men. It is rather remarkable that in most of these cases the infection was a primary one, attacking healthy valves, and not superimposed on old valvular lesions. Some cases of the latter and more common variety in civil practice were, of course, seen, both clinically and in the post-mortem room; but the point I wish to draw attention to is that an appreciable number of cases of primary acute infective endocarditis of the well-known type occurred in unwounded men with cardiac valves showing no signs of previous disease and where the source of the infection was not discovered. No septic focus was found in such cases, and they were not the sequel of pneumonia. Further, so far as my experience went, such cases were more frequent than cases following as a result of a septic wound, and they not uncommonly ran an acute and rapid course clinically.

CEREBRO-SPINAL FEVER.

Cerebro-spinal fever is a malady of great clinical interest and of considerable military importance, and it is a disease that presents several problems still awaiting solution. The earliest cases in the British

Expeditionary Force were seen in the late autumn of 1914, and it may be of some interest that in the very first batch of cases seen there were some that presented anomalous features, not only in their initial symptoms and mode of onset, but also in their clinical course and in the nature of the cerebro-spinal fluid.

Anomalous Cases.

Anomalous cases presenting similar features were seen from time to time throughout the campaign in association with other cases presenting the more classical and well-known symptoms of the disease, and it is to a certain group of such cases that I desire to direct your attention. This group of cases presented a distinct and fairly uniform picture of a malady with a sudden onset, with fever, headache, and vomiting, together with pains in the limbs of varying severity.

The patient rapidly passed into a condition of apparently considerable gravity with partial unconsciousness, or in the less severe cases into a stuporose condition with imperfect realisation of his surroundings. In all cases there was quite definite and marked retraction of the head, and the pulse-rate was usually slow. These cases always resembled closely cases of undoubted cerebro-spinal fever of a moderately severe type, and the more severe forms with a very sudden onset were practically indistinguishable clinically from cases of cerebro-spinal fever. One point that always made a positive diagnosis of cerebro-spinal fever a little doubtful in such cases was that Kernig's sign was not usually of the absolutely definite character—that is, associated with cerebro-spinal fever. In other words, the fixity or the rigidity of the knee was of a more plastic character and not of the locking character associated with cerebro-spinal fever. Nevertheless, the physical signs, including Kernig's sign, the initial symptoms, and the severe illness were all often so closely similar to those of true cerebro-spinal fever, that an accurate diagnosis was impossible in many cases without lumbar puncture. Lumbar puncture in these cases always yielded the same result. There was a considerable increase in the amount of cerebro-spinal fluid obtainable on puncture, and the fluid was under great pressure, but the fluid not only showed no abnormal cell elements, and no organisms were obtained on culture, but it was always extraordinarily clear and limpid in character. The quantity obtained was always large and sometimes very large, as much as 100 c.cm. being withdrawn at a single operation. The lumbar puncture was followed by rapid improvement and subsidence of the symptoms, and in most cases convalescence ensued rapidly and immediately. In some few instances the lumbar puncture had to be repeated, but this was quite exceptional, and in all the cases seen—some 20 in all—recovery was complete and usually rapid, no case being fatal. In a few cases, and notably in one that occurred in a medical officer, there was, in addition, a painful rash. This rash was present in the trunk, arms, and thighs, and consisted of small raised red papules tender on pressure; the tenderness on pressure was such as to cause considerable discomfort to the patient.

These cases formed a very definite clinical group, and their true nature is very obscure; it is difficult to determine whether they should be regarded as a variety of cerebro-spinal fever, or as mere so-called meningismus associated with a variety of diseases, or as an independent affection. The uniformity of the clinical phenomena and of the course of the affection, together with the absence of any evidence of the presence of other diseases in the patients, makes it very improbable that the cases were of the nature of meningismus complicating some other disease. The workers on cerebro-spinal fever in this country have described cases where no organisms were found in the cerebro-spinal fluid and where this fluid was clear; but whether these cases were of the same type as those just described is not quite certain, although it is probable. Our cases were characterised by an extraordinary limpidity of the fluid, together with a notable excess in quantity and sometimes, as mentioned above, a very great excess. Further, in the cases described in England the meningococcus, although not found in the cerebro-spinal fluid, was found in nasal swabs; but this was not the case in a series of these cases examined in France, as the meningococcus was not found in throat and nasal swabs in a single case of this type. The fact that these cases occurred at the same time as other typical cases of cerebro-spinal fever is, of course, a strong argument for linking them together. The clinical point I wish to emphasise is

that these anomalous cases were often of a quite severe type with marked, and in some cases with urgent, symptoms, and that they were not by any means cases presenting only slight and equivocal signs or symptoms of cerebro-spinal fever; nevertheless, they were never fatal. Every clinician is familiar, especially during an epidemic of cerebro-spinal fever, with cases where the symptoms are suggestive of the presence of the disease, although they are not of a severe type, and where the results of puncture are negative and the patient rapidly recovers. The cases I have attempted to describe are not of this type, since they are often of a severe character, and during the first 24 or 48 hours of illness almost indistinguishable from cases of severe cerebro-spinal fever. I fear I am only able to give this short description of them and am not able to state positively their nature, although they seem to form a definite clinical group.

Difficulties in Diagnosis.

Cerebro-spinal fever sometimes presents peculiar and remarkable symptoms at its onset, and thus renders early diagnosis difficult. One of the most frequent of these anomalous types of onset is that in which dyspnoea is the leading symptom, and where other symptoms, such as headache and fever, although present, do not attract attention as they are comparatively slight; whereas the dyspnoea may be very marked and urgent. In some instances the dyspnoea is of sudden or, at any rate, of rapid origin and may be severe enough to cause the patient to sit up in bed. It is apt to be accompanied with some restlessness and probably some mental dullness and confusion. If due importance be not given to the presence of slight pyrexia such cases are very apt to be diagnosed as uræmic or even, as I have seen, as diabetic in origin, owing to the presence in the urine either of albumin or of some reducing substance. Several cases of cerebro-spinal fever of a very severe type and rapidly fatal have fallen under my observation where uræmia had been diagnosed on account of the severity of dyspnoea and the presence of mental dullness or stupor. In some cases the rash of the disease had been regarded as confirmation of the existence of uræmia. In all these cases the error was dependent upon the presence of albuminuria being regarded as proof of the existence of serious renal disease. In these cases with marked dyspnoea the dyspnoea is always very urgent and not infrequently it is a very early symptom. Such cases, so far as my experience goes, are very severe and usually rapidly fatal. There is no real difficulty in the diagnosis, as a complete examination of the patient reveals physical signs characteristic of the disease and lumbar puncture at once yields positive evidence. Cerebro-spinal fever may not only be confounded with uræmia, but it may also be confused with nephritis. The former mistake is merely an error in diagnosis and in the interpretation of certain signs and symptoms; but the confusion with nephritis is a more difficult problem, as it would seem that certain cases of cerebro-spinal fever may not only develop nephritis as a complication, but that in other cases for a certain period nephritis may be the only manifestation of the disease. Several instances of the association of nephritis with cerebro-spinal fever were seen, and in some the onset and cause of the illness was very remarkable. In the first place, nephritis may occur as a complication in ordinary cases of cerebro-spinal fever of moderate severity and running a normal course with the usual signs of declared and obvious meningitis. In such cases nephritis is also of the familiar type with or without anasarca. In 1915 I saw two such cases in adjoining beds with the late Dr. Carter, of Birmingham; in both the cerebro-spinal fever was of a severe type, and in the second week of illness the nephritis developed and was accompanied with very considerable anasarca. In such cases, however, both the meningitis and the nephritis are quite typical, and it is only that one occurs as a complication of the other. It is not this type of case that leads to error of diagnosis, but another type which is of greater clinical interest, and where the

initial manifestations of illness take the form of nephritis. The meningeal symptoms are at first absent, and only develop after the lapse of a week, ten days, or possibly even longer.

In these cases the onset of the disease is subacute, with headache, general pains, but not of great severity, possibly some initial vomiting and slight pyrexia. There is no sign of severe illness and no signs or symptoms suggestive of the presence of meningitis. The urine contains an appreciable, or it may be a considerable, quantity of albumin, together with epithelial and granular casts. Thus the diagnosis of nephritis is made and the patient's condition attributed solely to this. I have not seen anasarca in any such case, although it certainly may occur in the nephritis that develops as a complication in declared cases of cerebro-spinal fever. The patient with the supposed simple nephritis is not apparently very ill, but is apt to be very quiet and apathetic, and the headache and slight pyrexia persist. The headache becomes more intense, and then, after a variable period, sometimes a few days, in others longer, and in one case after three weeks, symptoms such as very intense headache, stiffness of the neck and possibly of the limbs become much more marked and reveal the true nature of the disease, and this is confirmed at once by lumbar puncture. Although the meningeal symptoms develop and increase, the nephritis does not, the renal lesion would seem to be always of very moderate intensity, and certainly not rapidly progressive. Several instances of this "nephritic" variety of cerebro-spinal fever came under my notice, and some were fatal, including one in a nurse.

Two other anomalous modes of onset in cerebro-spinal fever may be described shortly, although they are both rare.

In one the onset of the disease was very sudden with severe and repeated diarrhoea, accompanied with some abdominal pain and headache not of a severe character. The diarrhoea was profuse, and its sudden onset, with the fact that there were no other marked symptoms, led to the suspicion of some food poisoning being its cause. The diarrhoea lasted some 12 hours, and the next day the patient, a medical officer who had been in contact with cases of cerebro-spinal fever, expressed himself as having recovered from the attack; but he looked ill and had some headache and considerable albuminuria; the diarrhoea, however, had ceased, and only very slight pyrexia, the temperature being just over 99° F., was present. No signs of cerebro-spinal fever were observed although looked for, as the disease was rather prevalent at the time. During the next two or three days no symptoms developed beyond the fact that in the afternoon the headache became more marked and the temperature rose to 100°, and the patient began to complain of aching and stiffness in his limbs; these symptoms were absent in the morning. On the sixth day of illness the headache became more intense and lumbar puncture revealed the true nature of the disease, and the case was fatal at the end of another week.

A Remarkable Case.

The most remarkable case from the clinical standpoint of this disease seen by me was one where an officer had a febrile illness of some five weeks' duration with absolutely no signs of any kind beyond the presence of the pyrexia.

The fever was very high, reaching 105° F. on several occasions, and there was always a large daily oscillation so that the chart greatly resembled some septic infection. He had very few symptoms and for a considerable time did not apparently suffer from the pyrexia. I often saw him sitting up in bed reading, writing, &c. All the usual examinations, including repeated blood cultures, yielded negative results, and during all these weeks of fever no diagnosis was made. After some five weeks of pyrexia of this septic type he suddenly developed rigidity of the neck, accompanied with severe headache and vomiting, and lumbar puncture revealed the presence of meningitis, and the organism was recovered and successfully grown. After a very prolonged illness of a severe type and necessitating several lumbar punctures he ultimately recovered completely and served in the Air Force at the front. I have seen him recently, when he was in vigorous health and actively engaged in work.

In bringing to your notice these anomalous forms of cerebro-spinal fever I have purposely excluded the considerable number of cases where failure to recognise the malady depended only on the mere confusion of meningitis with such well-known diseases as rheumatism or influenza—in other words, mere errors of diagnosis made when confronted with the ordinary forms of meningitis, and when the apparent slightness of the symptoms failed to warn the observer that they

were really dependent upon such a serious cause as cerebro-spinal fever.

Etiological Significance of Anomalous Cases.

The study of these anomalous cases is of some interest in relation to the problem of the ætiology of the disease, and would seem to confirm the idea that the danger of direct infection from cases of the malady itself to others is not really very great. The anomalous cases I have described were necessarily not recognised in their early stages in many instances, and during this period they were often in general wards with no special precautions; yet the disease did not spread to others, even when, as in some cases, their stay in such wards was prolonged to several weeks. Thus, in some of the cases with an onset simulating nephritis a patient might be in a general ward for as long as two or three weeks, yet I am not aware of the disease having spread to others in any such case. This is in harmony with the rarity of the infection spreading from declared cases to others in close contact with the sick—e.g., medical officers and nurses. Although the direct spread of infection from the anomalous cases was not observed, nevertheless it is possible that such cases may lead to the development of the disease indirectly in the same way as the more usual types of the malady, and therefore their prompt recognition and isolation is equally important in all circumstances and more especially perhaps in military medicine.

TUBERCULOSIS.

The existence of large hospital camps afforded an opportunity for obtaining some statistics as to the incidence of tuberculous lesions both active and quiescent, owing to the performance of post-mortem examinations in the thorough and complete manner that is customary as a routine in civil hospitals, and it was possible for this to be done in these hospital camps, thanks to the centralisation of such work under the superintendence of a specially appointed medical officer with experience as a pathologist. The full and complete results of this work will doubtless be published later, and I only wish now to allude to certain facts of interest. I am indebted to the courtesy of Dr. T. H. G. Shore, who was the officer in charge of the morbid anatomy in the Etaples area, for some statistics that are of interest. Clinical observation in the hospitals showed that tuberculosis was not a very common ailment, but the large number of men dying from wounds after severe fighting, gave an opportunity probably never before obtainable, of getting reliable information as to the frequency of the presence of tuberculous lesions in the apparently healthy. The detailed study of the autopsy statistics of the war and especially those from large hospital centres where the morbid anatomy work was organised, will give valuable information on this and on other questions, but such studies are necessarily at present incomplete. The statistics I am now going to put before you are merely those of the incidence of tuberculous lesions as proved by post-mortem examination, in cases of death from all causes, including therefore deaths from wounds, accident, disease, and disease includes cases of death from tuberculosis. In other words, it records the incidence of tuberculous lesions as determined by post-mortem examination in the British Expeditionary Force. These observations were carried out during the later years of the war—i.e., in 1917 and 1918—that is to say, at a time when the personnel of the armies was perhaps not quite of the same standard as in 1914 with the old Regular army, or in 1915 with the original Territorial army and the original so-called Kitchener armies. Nevertheless, the army population of 1917 and 1918 was still a selected population, both as regards age and physique, and was not comparable to the mixed population from which a London hospital derives its patients.

Statistics of Tuberculous Lesions Post Mortem.

The total number of post-mortems performed was 2121, and in 256 cases a tuberculous lesion of some kind was present—that is to say, in 12 per cent. of the cases. In the 256 cases 62 cases are included where death was the direct result of the tuberculosis; in other words, there were 62

cases of fatal tuberculous disease amongst the 2121 post-mortem examinations made in deaths from all causes. Thus, although the total incidence of tuberculous lesions was some 12 per cent. of the total post-mortem examinations made, tuberculous lesions were present in men dying from wounds or from some acute disease other than tuberculosis in about 9 per cent. of the total number of cases examined post mortem. Dr. Shore has analysed these figures to some extent, and his results show that the actual incidence of tuberculosis is much the same in the British, Canadian, and Australian Forces. In these three separate forces the incidence varies only between 11.4 per cent. and 11.8 per cent. In the New Zealanders the incidence was much higher—i.e., 17.8 per cent.—but the number of cases examined was small—i.e., only 56 post-mortem examinations were made in New Zealanders, with 10 cases where tuberculous lesions were present, so that it would be unwise to draw any definite conclusion from so limited a number. In a series of 1513 post-mortem examinations yielding 146 cases with tuberculous lesions the situation of the lesion was as follows:—Pulmonary, 113; glandular, 74; miliary, 14; peritoneal, 14; renal, 20. Expressed in percentages: Pulmonary, 76.7 per cent.; glandular, 50.7 per cent.; miliary, 9.6 per cent.; peritoneal, 9.6 per cent.; renal, 13.7 per cent. If these are expressed as percentages of the total number of post-mortem examinations in the series the following are the results:—Pulmonary, 7.5 per cent.; glandular, 4.9 per cent.; miliary, 0.9 per cent.; peritoneal, 0.9 per cent.; and renal, 1.3 per cent. In the series of 1513 post-mortems there were, as mentioned above, 113 cases in which the tuberculous lesion was pulmonary. If these pulmonary cases are further analysed the following results are obtained:—In 27 cases (i.e., 23.9 per cent.) the lesion was active; in 21 cases (i.e., 18.6 per cent.) the lesion was chronic; and in 65 cases (i.e., 57.5 per cent.) the lesion was quiescent. In the 74 cases of glandular tuberculosis it is perhaps worth recording that 34 were thoracic, 32 abdominal, and in 8 cases both sets of glands were involved.

These statistics not only give results as to the incidence of tuberculous lesions in the army, but they may perhaps also be used, doubtless with many qualifications, to throw light on more abstruse questions, as, for instance, the different degrees of resistance of different races to the virus of tubercle. Dr. Shore has classified the results according to race; thus a small number of post-mortem examinations were made on natives of South Africa, of the West Indies, and of New Zealand Maoris. The numbers are small, but the incidence of tuberculosis was high; but although this is of interest, the most striking fact was that in all cases where tuberculous lesions were present the patient had died from tuberculosis, and no instance of either a chronic or a quiescent lesion was found on post-mortem examination of these native races. Further, in the white races the death-rate from tuberculosis presented considerable differences.

Thus although the percentage incidence of tuberculous lesions in the British Canadians and Australians was much the same, varying, as stated above, from 11.4 per cent. to 11.8 per cent., the death-rates in these different forces were very different. In the British, in a series of 1650 post-mortem examinations, there were 188 presenting tuberculous lesions, and in 31 these were the cause of death—i.e., the death-rate was 16.5 per cent. of those affected. In the Canadians the corresponding figures were: post-mortems 220, tuberculous lesions 26, deaths from tuberculosis 7, a percentage, therefore, of 26.9. In the Australians: post-mortems 93, tuberculous lesions 11, deaths 5—i.e., a percentage of 45.4. The figures for the New Zealanders are very small: post-mortems 56, tuberculous lesions 10, and deaths 8—i.e., a percentage of 80.

Thus the resistance of the men in the British Forces would seem to have been the greatest, and that of the natives of South Africa, West Indies, and Maoris the lowest, and that of the men coming from the Dominions intermediate between these two extremes. It would seem, however, that they also presented differences amongst themselves—e.g., the Canadians and the Australians.

DISEASES OF THE BLOOD.

A few cases of pernicious anaemia were seen, but the number was very small; on the other hand, an appreciable number of cases of leukaemia occurred, and there are certain points of interest with reference to these cases. Thus only one case of the more common form of the disease—i.e., chronic spleno-medullary leukaemia—was seen; all the others were instances of acute leukaemia of more or less sudden onset and rapidly fatal

after an illness of only a few weeks, and often of only two or three weeks.

These cases were of a very uniform type, characterised by moderate fever, great weakness and prostration, often of sudden and always of rapid development, with an intense and very characteristic pallor, and generally some purpura. In some cases the occurrence of purpura was the first sign to attract attention, but more usually it was found on examination in a patient who reported sick owing to rapid prostration and loss of strength. The purpura was usually moderate in degree, but not infrequently it was of the type of purpura hæmorrhagica, and hæmaturia, sometimes profuse, and epistaxis were the most common forms. Hæmorrhage from the bowel also occurred. The purpuric eruption in the skin was of the usual type, but I was struck with the frequency of the presence of purpuric spots in the face, a phenomenon that is usually regarded as very exceptional. Purpuric hæmorrhages in the gums and in the tongue were also not uncommon, and some of the cases suffered from the severe stomatitis and sloughing of the gums that is such a well-known feature of the disease. All the cases showed the well-known and characteristic changes in the blood, such as the very great diminution in the number of the polymorphonuclear cells and the enormous increase in the number of large transitional lymphocytes with a large nucleus. I saw no case of acute leukaemia where the increase and number of white cells was due to an increase affecting only or mainly the small lymphocytes. The glandular enlargement was usually moderate and never extreme, and clinically the spleen was either not enlarged or only to a moderate degree. On post-mortem examination the thymus was in all cases persistent and enlarged.

It is of interest that so far as my experience went acute leukaemia, and especially that form of it characterised by purpura, was seen much more frequently than the ordinary forms of leukaemia.

An Obscure and Rare Disease.

In relation to this blood disease mention may be made here of an obscure and rare disease that was seen in two and possibly in three instances.

This malady was characterised by a febrile illness, somewhat resembling in its gradual onset and clinical course enteric fever. This similarity was shown not only by the gradual onset and the character of the temperature chart, but also by the occurrence at the onset and in the first few days of illness of some diarrhoea. The pyrexia was considerable, reaching 103° F. in its daily oscillations. The pyrexia lasted several weeks, during which the spleen slowly and gradually increased in size, and in at least two cases not only reached the middle line of the abdomen but passed well beyond it. The splenic enlargement was quite comparable to that seen in ordinary cases of spleno-medullary leukaemia. The patient presented no marked symptoms beyond those due to the pyrexia and a moderate degree of anaemia. Blood examination revealed a condition similar to that seen in splenic anaemia, a diminution in the number of red cells, and a considerable leucopenia, the white count falling to 3000. Repeated examination of the blood and stools failed to detect any organisms of the enteric group, and the Widal reaction was also uniformly negative.

The cases presented considerable resemblances to those of splenic anaemia, pyrexia, great splenic enlargement, anaemia, and leucopenia, but this diagnosis can scarcely be correct, since after an illness of many weeks the pyrexia declined and the spleen slowly returned to its normal size. One such case was not only watched throughout the illness, but it was ascertained that he was quite well one year after leaving hospital. The nature of these cases is obscure, as it would seem that enteric fever, splenic anaemia, and certain tropical affections could all be excluded, as not only was the search for parasites negative, but the cases were seen in young soldiers who had only served in France.

SALARIES OF SCHOOL MEDICAL OFFICERS.—At the last meeting of the Devon Education Committee it was decided to appoint a subcommittee to consider the question of the salaries of the medical staff. The Devon Education Committee some time ago decided to give their medical officers £410 per annum, but owing to resignations they have had to give a locum tenens 10 guineas a week, or £520 a year. The chairman said that they could not get medical officers for £400 per annum, and another member remarked that the salaries would have to be increased. Eventually the subcommittee was appointed, and it appears that the Education Committee will in the future have to pay the usual salaries given to school medical officers.

HOSPITAL TREATMENT OF THE PSYCHOSES AND PSYCHONEUROSES.

SUGGESTIONS FOR BRINGING THEM WITHIN THE SCOPE OF A GENERAL SCHEME.

BY EDWIN GOODALL, C.B.E., M.D. LOND., B.S., F.R.C.P. LOND.,

MEDICAL SUPERINTENDENT, CARDIFF CITY MENTAL HOSPITAL.

THE following suggestions are concerned particularly with patients other than in the metropolis who are either of the usual hospital class or not able to pay more than from two to five guineas a week, most of them only able to pay such fees for about six months. Under the designation "psychoses" would be comprised the various varieties of mental disorder, mainly in an early phase. The psychoneuroses would be illustrated by the borderland states, with mixed mental and "nervous" manifestations; psychasthenia or neurasthenia, with obsessions or imperative ideas; morbid doubts and fears; tics, with psychical perversion; psychoses associated with disorders such as Graves's disease or chorea; mixed nervous and psychical disorders after mental or physical shock; psychoses associated with minor epilepsy. All these conditions are accompanied by physical reduction, more or less in degree. Those interested in neurology (with which these suggestions are not concerned) may consider that its claims to be dealt with under a general scheme require to be pressed.

The medical requirements of cases of the psychoses and psychoneuroses have never been adequately met in this country. The time would seem opportune, I would fain say propitious, for insistence and persistence on their behalf. Greatly daring I shall scarcely be if I maintain that these patients constitute the most neglected section of the sick community. How could they be comprised in such a scheme as has been sketched in the Interim Report of the Consultative Council on Medical and Allied Services? In view of the stepmotherly treatment which has been meted out to patients suffering from these maladies hitherto, those whose practice lies amongst them have, no doubt, perused the Report, and especially with a view to ascertaining whether their claims to benefit under the projected scheme have been adequately dealt with. On consulting the Report it will be seen that the only reference made to mental disease is under "Supplementary Services" (pars. 14 and 74). Amongst these services come "hospitals for curable or incurable mental disease." So that the patients now referred to would merely be provided for in a supplementary fashion, together with, for instance, cases of tuberculosis, of infectious disease, and of epilepsy suitable for colony care. Incurable mental disease could be adequately provided for thus, but not curable. The psychoses and psychoneuroses together constitute a vast and oppressive liability, which, I maintain, cannot be discharged through the medium of a mere supplementary service. They were long since shunted on to the sidings of the main traffic of disease, where they have remained, mainly stationary. They, with their medical and nursing services, have long suffered, and still suffer, all the evils of segregation. What is now suggested amounts to a perpetuation of these evils in a milder form. Being at present outside medical society, it is proposed to admit them to its fringe. I would claim, with the full blatancy of the most truculent of trade-union leaders, "full recognition" for them; full provision, alike in primary, secondary, and teaching centres. I affirm that no adequate reason against their inclusion in any way worthy to be set against their crying needs can be adduced.

Application of the Three-centre Scheme.

One may conceive cases of the psychoses and psychoneuroses as occurring in a certain area, and provision being made for them under the general scheme of the Interim Report as follows (existing buildings, modified

or enlarged, to be used for the present; the psychiatric clinic would require to be a new building):—

(a) In a rural district, where the most modest requirements of an indoor clinic or hospital are scarcely available and the needs of patients would have to be met under the next heading.

(b) In a small town able to furnish a building worthy to rank as a hospital (primary centre). Here there would be comparatively modest equipment for diagnosis, clinical laboratory work, and medical and surgical treatment.

(c) In a large town containing a hospital in an adequate sense, with visiting medical staff, some with training in special directions; a resident medical officer or two; some of the nurses specially trained in various directions, with one or two capable of conducting, with some tuition, a class of Swedish exercises; with masseuses; with laboratory facilities of a fairly extensive kind and technical apparatus; with out-patient department—in fact, a hospital equipped with everything entitling it to rank as a secondary centre.

(d) In the town wherein is situated a medical school, with its associated hospital, research and laboratory workers, teaching facilities, and consultants; the teaching or tertiary centre, to wit; the *ne plus ultra* when the lacking clinic in psychiatry, complete internally, with its out-patient department in association with other like departments of the hospital, shall have been established.

Those who have experience, be they general practitioners or specialists, of the difficulty and inappropriateness of dealing with—I will not say treating—these patients in their homes will fully appreciate how much the application of the three-centre scheme will mean to them. In my judgment, the first desideratum is to get them away from home surroundings and from relatives. Is there any class of invalid to whom this applies with equal force? Solve this difficulty by providing for these cases on the three-centre system, and their treatment is at once placed on a sound footing, and the haunting fear of the alternative to home—the asylum—will fade, treatment will commence in reasonable time, and less will be heard of the need for extending asylums. In making such provision, regard must be had to special requirements. Whether cases of the psychoses and psychoneuroses are received under (b), (c), or (d) of the above scheme, they will require facilities under the following headings:—

A room or ward so arranged, supervised, and administered, that means of self-injury are reduced to a minimum; one or more single rooms for isolation; a nurse or nurses, trained in mental disorders (preferably with general training also; the combination is more and more to be found); one or more masseuses, according to requirements; facilities for open-air rest in bed, for regular weighing; douches, open baths, available for prolonged warm-bath treatment—under (d) baths maintaining a constant level and temperature; a garden for exercise and occupation; facilities for indoor occupation, especially handicrafts—under (d) suitable shops, sewing-room and gymnasium, and other facilities for treatment under this special heading, which need not be specified here.

As regards *diagnosis and medical advice*, the principal and second medical officers of the nearest public mental hospital should be available for consultation, as also the director, or one of the staff, of the nearest psychiatric clinic. I would suggest that the domain of the psychoses and psychoneuroses is quite peculiarly one in which the general practitioner finds himself, and will continue to find himself, in need of expert advice, and that he will not commonly take the sole responsibility of deciding how the patient should be disposed of. I think a special case can be made out for an arrangement under the general scheme, with the agreement of the controlling authorities of mental hospitals and psychiatric clinics, whereby a reasonable fee is payable to the staff of these institutions for this consultative work out of local or State funds, in cases where the patient has no means. In suitable cases, and where distance allows, the patient can be sent by his doctor to the out-patient department of the nearest psychiatric clinic, or of the nearest mental hospital, should such department exist at the latter, and advice as to his disposal be thus obtained. However obtained, expert advice could decide whether the patient should be dealt with in hospital under (b), (c), or (d); whether—exceptionally—by reason of the gravity of his symptoms, notwithstanding their recent origin, or of insufficient accommodation being available under (d), the case should go to a mental hospital. When the case falls to be treated under (b), his own doctor should look after him, whenever possible, expert advice being available. Under (c) the patient will be under the care of a member of the visiting staff. Expert advice in this instance will, for a time, only be available from the mental hospital and psychiatric clinic, the senior staff being placed

on the visiting staff of the hospital. But these clinics will in time furnish specialists for the large towns, who will be on the staffs of the hospitals with psychiatric wards. The consulting work of the district would be done by the director of the clinic and by these specialists. As consulting work is an essential part of the recommendations of the Interim Report the need for clinics in psychiatry, in this instance for the training of consultants, is once more emphasised.

It is highly desirable that patients who are convalescent from the maladies here dealt with—and no doubt the same is true of most diseases—should not return direct to their homes, but through a convalescent home or sanatorium. Recuperative centres are, I observe, recommended (para. 74) in the Interim Report.

Illustrative Cases.

The following brief descriptions of patients dealt with by me at the newly established out-patient clinic in psychiatry of King Edward VII. Hospital, Cardiff, within the last two months may afford examples of cases susceptible of care and treatment on the lines indicated. It will be observed that all should have sought advice much earlier. The provision of rational facilities for care and treatment should go far to remedy this drawback.

Cases 1 to 6 could be treated under heading B or C of the above scheme.

CASE 1.—A. B., male, aged 25, single; commercial traveller. Mother had epilepsy. Five years ago attack of "religious mania" and in the county asylum for three months; remained well till two years ago, when he became "altered," but was able to go on working; present condition dates back three months; at present shows some exaltation; writes lengthy letters to distinguished people; believes himself to be a person of some importance; tends to restlessness; is forgetful, and unable to apply himself; quarrels with his employers; there is evidently general physical reduction. Is a candidate for an attack of mania unless promptly cared for. At present can only be treated at home.

CASE 2.—C. D., female, aged 20, single; domestic servant. No noteworthy history of mental or allied disorders in family. About three years ago, whilst in a situation, was taken advantage of by her employer. Had a child in consequence (two and a quarter years ago); went "strange" and has been "strange" since. About 18 months ago said to have had what appear to have been choreiform tremors in the left limbs. Mother states that the girl tried to strangle herself three weeks ago; also took some poison; said to be impulsive and vicious. At the present time tremors in all limbs, more marked in the left hand; probably most of the tremor removable by psychotherapy. Considerable physical reduction, morbid doubts and fears, with associated depression, and a considerable neurotic element. Patient very desirous of being admitted to a hospital; begged not to be sent home; recognised she was a burden to her mother, who had already sent her once to a union infirmary, for lack of a more suitable place. At present can only be treated at home.

CASE 3.—E. F., male, aged 25, single; coal-tipper. No noteworthy history of mental or allied disorders in family. Well and able to earn his living until June, 1919, when he met with a severe accident, sustaining compound fracture of the femur; the mental condition is referred back to this. Father states that patient was normal during puberty and adolescence, although rather backward at school; has left club-foot.

Present condition dates since last Christmas; gradually became depressed, crying for a trifle; morbid anxiety and fear; lack of energy; restarted work ten weeks ago, but unable to continue; thinking people staring at him, that he was of "no use"; afraid to see others; talking to himself; sleeping irregularly, and capricious re food. Physically much reduced; marked tremors of tongue and of facial muscles when speaking. Wassermann in serum negative. Present mental condition is one of partial dementia.

There happened to be a hospital in his district, and it was recommended that he be taken in there and treated by his medical man, who referred the case to the out-patient clinic, with occasional reference to me, although the facilities available at the hospital are not all that could be wished.

CASE 4.—G. H., male, aged 40, married; engine-driver. No noteworthy history of mental or allied disorders in family; states that he has had slight attacks of nervousness and "lowness" the past four or five years at different times, but he has never had to leave work. Present condition dates to about six months ago, and is ascribed by the doctor to influenza followed by a rather severe attack of pneumonia; more or less since then has complained of inability to attend to work, to take responsibility; inability to remember; feelings of depression, with loss of interest in work; sleep and appetite have been failing.

The present state may be described as psychasthenia; he complains of various morbid sensations in various parts of his body, and these can be suggested to him; is in a state of doubt and anxiety; says that everything is "closing in"; is entirely introspective; believes that his condition is traceable to masturbation in youth; says he would sooner be dead if his condition is incurable. Physically considerably reduced.

There being a hospital in his district (with the same limitations) the same recommendation was made as in Case 3.

CASE 5.—J. K., female, aged 20, single. Occupation nil. Family history: Mother states she has had five miscarriages (from six weeks to six months); no evidence of syphilis; one brother, aged 22, of the patient had a "nervous breakdown," for which he was discharged from the army; one brother (? the same), had night terrors; otherwise no noteworthy history of mental or allied disorders in family; mother observed to have malformed incisors of upper jaw, the teeth projecting to a marked degree. Patient

described as having been late in learning to walk, but not in any other respect; also had night terrors earlier in life. Menstruation commenced at the age of 12; the present condition is worse at the menstrual periods. This attack (the first) is traced to overwork or mental strain in a clerical office, together with an attack of influenza. In August, 1918, matters came to a climax; it was noticed that she was unable to do her work; the present condition has lasted, off and on, since then. The hard palate is decidedly narrow and vaulted. The anterior nares are extremely narrow, the left is almost occluded; patient very pale and looks reduced; the mother states she has lost weight.

The present condition is one of marked confusion and disorientation; her conversation is jerky and inconsequent, at times almost incoherent; she is restless and fidgety; unable to fix attention; occasionally laughs and mutters to herself; at times is impulsive, and has thrown articles whilst at the dinner-table. (The condition is not one of dementia præcox.) She makes frequent reference to her relationships with some youth she appears to have met, and this circumstance may have played its part in precipitating the attack. The treatment at home, under the best conditions available, is producing a gain in weight, and otherwise giving indication of favourable results.

CASE 6.—L. M., female, 41, married; housework. As regards family history, two brothers are stated to have died of convulsions when a month or two old; one sister to have died of the same. The patient herself was a somnambulist as a girl; once walked up the street at night in an unconscious state. This attack (duration three to four months) stated to have followed influenza; menses still regular; the patient now complains of various morbid sensations, such as "swellings in the neck," "weakness of the legs," "machinery in the head"; these distract her attention and cause exasperation with uncontrollable impulse, so that she is reported to have put her head in a gas oven once and to have attempted to injure herself with a razor. At present can only be treated at home.

Cases 7 and 8 are probably best adapted for treatment under heading D.

CASE 7.—N. O., female, aged 19, lives at home. Mother states she had ten children; four died in infancy, two with seizures; one of the six living started fits aged 2 years, and had them rarely until aged 21; none since (now aged 26); paternal grandmother of present patient died in county asylum; paternal uncle now there; paternal grandfather committed suicide; intemperance in father's family; stated to be some consumption on the mother's side. Mother a very intelligent woman. The patient could have earned her living (as far as intelligence goes) had it been necessary; she started having fits three years ago at night and early in the morning rarely (only one to two weekly). Once had a series of them. The mother attributes the first seizures to shock due to an assault, apparently with attempt to rape; regular after the above, but for last two years amenorrhoea. Leucorrhoea since last May; was in the county asylum for a while last year. There is no marked mental deterioration. Transferred to the gynaecological clinic. Uterus anteroverted, possibly endometritis; treatment of the amenorrhoea suggested. Requested the gynaecologist to continue treatment for the present, and pass her back to the psychiatric clinic in due course.

CASE 8.—P. Q., male, aged 35-40; bank employee. Served in Mesopotamia during the war; no history of illness or wounds; no family history of mental or allied disorders admitted. First attack; always of a worrying temperament; present condition has been going on for several months; believes his books will not bear auditing; that they have been falsified by him; that this and similar dishonest deeds of his are about to be brought to light; the fear of what will happen to his family oppresses him; is entirely self-centred and incapable of attention; lies in bed moaning. The day before I saw him he wandered from home, returning late with his leg-coverings soaked; said he had walked into the sea, not having control of his actions; has no clear recollection of events. The usual general physical reduction exists, but no specific disease. Certified to a registered hospital for the insane, where he is going on well.

Conclusion.

If the psychoses are to be dealt with under a three-hospital system a modification of the Lunacy Laws will be necessary, and therefore the recent presentation in the House of Commons of the Ministry of Health (Miscellaneous Provisions) Bill, which authorises under Clause 10 the care and treatment of cases of mental disorder "incipient in character and recent in origin," notwithstanding the provisions of any existing Act, is welcome. I observe nothing in the proposals of the Minister of Health which would render impracticable the scheme of care and treatment herein outlined, though the observance of certain formalities, such as the notification of reception, the production on authorised demand of written consents and certificates, is likely to prove irksome and to cause resentment at the outset. No vivid imagination is needed to forecast the administration hereafter, in whole or in part, of a three-hospital system, under Clause 11 of the Bill, by local authorities. These should meantime be diligently advised to insist on provision under any such system for cases of the psychoses and psychoneuroses. Superintendents and administrators of hospitals might be well advised to contemplate their future responsibilities under the new order of things. The annual production of "consents" and "certificates" will be a bagatelle compared to the quarterly requirements of the representatives of the ratepayers.

LOBAR PNEUMONIA.

A CLINICAL ANALYSIS OF 558 CONSECUTIVE CASES.

BY ADOLPHE ABRAHAMS, O.B.E., M.D. CANTAB.,
M.R.C.P. LOND.,PHYSICIAN TO THE ROYAL CHEST HOSPITAL; ASSISTANT PHYSICIAN
TO WESTMINSTER AND HAMPTHEAD GENERAL HOSPITALS;
LATE MAJOR, R.A.M.C., AND DISTRICT CONSULTING
PHYSICIAN, ALDERSHOT COMMAND.

THAT one observer should have been privileged to see within two and a half years no fewer than 558 cases of lobar pneumonia is, I venture to think, sufficiently confirmatory of the view that medical officers during the past war were afforded exceptional opportunities to practise medicine upon an intensive scale. I have selected for consideration a disease which is particularly suitable for statistical investigation. Lobar pneumonia presents features which make a correct diagnosis a matter of practical certainty; it occurs sufficiently frequently to provide a conveniently large number of figures from which to draw conclusions; and as regards incidence no special peculiarities of military life can be said to vitiate comparisons with its occurrence in civil practice. From the personal standpoint it is a matter of some importance that every case was seen from the first day (and generally from the first hour) of its arrival in hospital, and that the progress throughout to its termination was systematically investigated. For these reasons errors of observation became reduced to the lowest possible limits—the errors of observation of one clinician; whilst the circumstance that the treatment of every case was actually ordered or personally supervised by the same person removes any implication as to individual skill, and so affords an indication as to the dependence of mortality upon details which relate solely to the patients themselves.

I have excluded a few cases which occurred in the Aldershot Command which were probably cases of lobar pneumonia but about which some doubt in the diagnosis remained to the end, and no case is comprised in my series which could not according to accepted criteria be legitimately included. The investigation terminated suddenly in October, 1917, on my transference from the Aldershot Command when urgently mobilised for service overseas; and on my return to the Command for the rest of my military service the supervention of the influenza epidemic, with its anomalous pulmonary complications, rendered it impossible to differentiate unequivocal cases of true lobar pneumonia.

It must be admitted with regret that all the advantages afforded by this unique opportunity were not realised. Attention was from the outset particularly directed to clinical features. Much might have been done, however, to trace the connexion between incidence and climatic peculiarities, seeing that a selected body of men living under identical conditions was under consideration. Undoubtedly, had adequate meteorological observations been utilised many interesting facts would have emerged. But in the earlier months of the investigation such possibilities were not appreciated. Furthermore, statistical inquiries during the war were not only discouraged but rigidly forbidden. It was, in fact, only recently that I was enabled to procure the necessary information as to the number of troops actually serving month by month in the Command during the period comprised. To have proceeded further in an endeavour to elicit certain details relating to individual units would at that time have demanded opportunities which for many reasons were not forthcoming. The exigencies of military service regarded a home hospital as mainly a pied-à-terre or distributing centre for medical officers proceeding overseas; the minimum of skilled assistance was therefore available, so that elaborate investigations of the patient's family history, past life, and other personal details were necessarily neglected. For the same reason pathological work was at this time reduced to the lowest possible minimum, and the frequent changes in personnel precluded any systematic research.

For these reasons, then, my contribution is almost entirely clinical; nevertheless, I think the investigation of so large a number in so comparatively short a time may not be without interest and perhaps value, more especially when it is emphasised that conclusions are based upon cases drawn from a relatively selected population as regards age and physique, all living under practically identical conditions.

Incidence.

Table I. illustrates the incidence of cases month by month and at the same time comprises the distribution according to age. The average strength in the Command is also exhibited in order that the proportion of cases to total population can be scrutinised. The table also shows the mortality according to incidence, and briefly analyses the death-rate throughout the series according to the age of the patients.

A contemplation of this table leads to some rather bewildering and at first sight inexplicable results. In the first place, it will be seen that there is no evidence of a regular seasonal incidence. It is difficult to explain the large number of cases encountered in May, 1915, a preponderance which is not apparent in the corresponding month in 1916 and 1917. Contrast also April, 1916,

TABLE I.—Incidence and Mortality according to Age and Season.

	Under 20.	20-30.	30-40.	40-50.	Above 50.	Total cases.	Monthly strength of Aldershot Command.	Deaths.

Total	148	213	146	49	3	558	—	61
Deaths	9 (6.1%)	21 (9.9%)	20 (13.7%)	9 (18.4%)	2 (100%)	61 (10.9%)		

with April, 1917, and, as an even more striking example, November, 1915, and November, 1916. One might have suspected as a possible explanation of the fluctuating numbers corresponding variations in the total number of troops present in the Command, but the figures which I have recently obtained show that such variations do not run *pari passu* with the incidence of the disease. The incidence must have depended upon a large number of different circumstances—possibly climatic conditions, temperature, humidity, prevailing winds, and so on, with which I am unable to deal. Above all, I am convinced that the incidence must have depended largely upon the physique of the troops stationed in the Command, which certainly varied enormously according to military exigencies. Had it been possible to take an exhaustive survey of the troops, particularly as regards

their category, I feel no doubt a definite relation between susceptibility and constitution would have been definable.

It is easy to explain the curiously high incidence in August, 1916, when no fewer than 25 cases occurred. During this month a Canadian contingent was transferred direct from Canada to the Command, and the change of climate appeared to have been badly resisted, for of the 25 cases 18 were Canadians. (The cases were typically croupous pneumonia, and there was no question of an influenzal element.)

My conclusion as regards physique is supported by a consideration of the length of service of men affected. Of course, the army during the recent war consisted for the most part of men who had seen no previous service, so that by April, 1915—when my investigations at Aldershot were begun—a huge majority of men in the Command possessed less than eight months' service, and throughout the war recent recruits dominated the strength of the Command. Nevertheless, these observations extended to September, 1917, by which time the war had been over three years in progress, yet the striking fact is obtained that of the total cases seen no fewer than 62 (i.e., 11 per cent.) fell sick with the disease *within 12 days* of joining up; 119 cases (21·3 per cent.) in less than one month from enlistment; 227 (50 per cent.) in less than six months; whilst, finally, no fewer than 523 cases (93·7 per cent.) had had less than 12 months' service. I suggest that the change to military conditions—exposure, overcrowding, and other factors inseparable from army life—naturally determined this susceptibility of the more feeble.

Detailed descriptions of general physique are not forthcoming, and I can only give a general impression in stating that over and over again I was greatly struck by the wretched development of the recruits who came in sick.

It will be observed that only two men over 50 are included in the series—one would naturally encounter few men of this age—and that both succumbed. The service of one man was 13 months; of the other 15 months. The total mortality (10·9 per cent.) compares favourably with the mortality encountered in cases of pneumonia occurring in the general population, which in 1065 cases collected in 1884 by an Investigation Committee¹ amounted to 1 in 5·5—i.e., 18·2 per cent.

Of 673 cases which occurred in the Middlesex Hospital between 1880 and 1889 116 died—i.e., 17 per cent., and annual variations between 12 and 24 per cent. were encountered. One would naturally expect a lower mortality in such a series of cases as the one now presented, for the men were to a certain extent selected, and, speaking generally, excluded the aged, debilitated, and alcoholic, and eliminated all the principal adventitious causes which contribute to fatality. My percentage of fatal cases constitutes an intermediate between the average population and a body of men scrupulously selected for their physique. Osler² quotes statistics of picked men in the German Army, where among 40,000 cases a mortality of only 3·6 per cent. occurred. (In the same place he gives the record of 658 cases occurring in 16 years at the Johns Hopkins Hospital with a mortality of 200 (30·4 per cent.))

Initial Symptoms.

In interrogating patients upon their arrival in hospital regarding the onset of their illness leading questions were at first as far as possible avoided and direct suggestions were subsequently put with reference to certain of the commonest symptoms. The following table of symptoms (Table II.) gives their numerical frequency and percentage of total cases.

Table II. calls for little comment. Pain in the side was generally, but not invariably, restricted to the side in which signs of consolidation subsequently appeared. Headache one would naturally expect to be of fairly frequent occurrence. In my series six suffered from pneumococcal meningitis, and in a further 25 cases the symptom was of such severity that a provisional diagnosis of cerebro-spinal fever was made and lumbar puncture performed.

A complaint of difficulty in breathing was very infrequent; bronchitis, as will be seen, was advanced as a definite initial symptom in 40 cases, and these, for the most part, were subjects who were chronic sufferers from chest trouble. In 13 cases the only complaint was of sore throat. Of the 9 patients who complained of

TABLE II.

Symptom complained of—	No. of cases.	Per cent. of total cases.	Symptom complained of—	No. of cases.	Per cent. of total cases.
Shivering ...	381	69·0	Pain in abdomen	31	5·5
Pain in side ...	345	60·0	Tonsillitis ...	13	2·3
Headache ...	196	35·6	Dyspnoea ...	11	2·0
Vomiting ...	181	33·0	Pain in legs ...	11	2·0
Cough ...	132	24·0	Hæmoptysis ...	9	1·6
Pains all over ...	50	9·0	Diarrhoea and vomiting ...	3	0·5
General malaise	42	7·6			
Bronchitis ...	40	7·0			

hæmoptysis one was a case of trauma to the chest wall; and, bearing in mind the type of condition subsequently seen in the influenza epidemic, it is not altogether unlikely that three were of influenzal origin.

In 7 cases pain in the abdomen was so severe that they were sent in with the diagnosis of acute appendicitis. Three actually underwent operation for this condition, the appendix being found free from disease; and 3 others reached the theatre and underwent preparation for operation. In all these "abdominal" cases unequivocal signs of lobar pneumonia appeared in due course. From these figures it would appear that the simulation of acute appendicitis is not so common as is sometimes suggested.

Condition on Admission.

It is the usual practice in the army to transfer to hospital with the least possible delay all men who report sick with pyrexia, save of the most trivial character. In certain units provision is conveniently made for the isolation of the sick for observation, and, as is well known, a certain type of man regards it as *infra dig.* to report sick until he is in a state of complete prostration. With these few exceptions, however, the large majority of my series were admitted to hospital a short time after the onset of the illness. The accompanying table (Table III.) illustrates the condition on admission as regards the degree of pyrexia on their arrival in the ward.

TABLE III.

Temp. on admission.	No. of cases.	Per cent. of whole.	Temp. on admission.	No. of cases.	Per cent. of whole.
Below 98°	15	2·7	102°-103°	155	27·7
100°	39	7·0	103°-104°	131	23·4
100°-101°	34	6·0	Above 104°	84	15·0
101°-102°	115	20·5			

The cases who exhibited a temperature below 98° were in a state of collapse, and with the rare exceptions of those who never rallied showed pyrexia of over 101° within six hours of admission. It will be observed that over 70 per cent. cases on admission showed a temperature between 101° and 104° and over 50 per cent. between 102° and 104°. A temperature higher than 105° was very infrequent, in three of my cases only.

Pulse-respiration ratio.—This is usually held to be typically about 3:1 in cases of lobar pneumonia. In my series, although variations were very frequent, in 80 per cent. of cases the pulse-respiration ratio was between 3:1 and 4·5:1. These figures are substantially lower than those given by Osler (2:1; 1·5:1) which I observed in about 12 per cent. cases only.

Knee-jerks.—A special investigation of this feature was made since it has been mentioned that loss of tendon jerks is a usual feature in lobar pneumonia and that the phenomenon affords a valuable method of differentiation from an acute abdominal condition. The knee-jerks were abolished in 138 cases (24·7 per cent.). They were feebly present in 69 cases (12·4 per cent.). They were present to a degree which might be described as normal in 248 cases (44·4 per cent.) and

they were definitely exaggerated in 103 cases (18.5 per cent.). I believe that the original observation (which I have been unable to trace) was conducted at a time when it was not customary to employ the now familiar "knee-jerk hammer," without which a considerable number of sluggish and even normal knee-jerks would be overlooked and so contribute to an apparently large number of cases of abolition of the knee-jerk. If the test is properly performed it would not appear that any diagnostic value can be said to be attached thereto.

Signs in the Chest.

The figures in Table IV. refer to the time of appearance of the earliest definite signs of consolidation, not suggestive features such as crepitations or slightly prolonged expiration. It will be seen that in nearly 80 per cent. cases signs appeared within four days of onset of

TABLE IV.—Time of Appearance of Signs of Consolidation.

Day of appearance.	No. of cases.	Per cent.	Day of appearance.	No. of cases.	Per cent.
Day of illness—			Day of illness—		
First	12	2.15	Sixth	32	5.7
Second	152	27.2	Seventh	24	4.3
Third	161	29.0	Ninth	1	—
Fourth	115	20.0	Signs completely absent	12	2.15
Fifth	49	8.8			

the illness. Although in 12 cases no signs of consolidation could be detected throughout the course of the illness these cases were from other features unmistakably cases of true lobar pneumonia.

Distribution of Areas of Consolidation.

It is, I think, generally agreed that the right lung is affected more frequently than the left. Osler gives in 100 post mortems: R. lung, 51 per cent.; L. lung, 32 per cent; both lungs, 17 per cent. These figures are a close approximation to mine (Table V.), which, it

TABLE V.

Area.	Cases.	Per cent.	Area.	Cases.	Per cent.
Right lower lobe	191	34.2	Left apex	1	1.4
Right apex	64	11.5	Both lungs	115	20.6
Left lower lobe ...	168	30.0	Signs absent	12	2.2

must be observed, however, correspond to clinical observations, not to more exact post-mortem findings. It is, further, universally maintained that the lesion of "double pneumonia" is more serious than when one lung only is affected. This is certainly supported by my series, for in 115 cases of double pneumonia 33 deaths occurred—viz., 28.7 per cent.—as compared with a mortality of 10.9 per cent. when all cases are considered.

Sputum.

Table VI. gives the day of appearance of typical rusty sputum. It will be observed that, as in the case of the time of appearance of physical signs, the second, third, and fourth days predominate. In quite a con-

TABLE VI.

Day of appearance of rusty sputum.	No. of cases.	Per cent.	Day of appearance of rusty sputum.	No. of cases.	Per cent.
Day of illness—			Day of illness—		
First	4	—	Sixth	48	8.6
Second	97	17.4	Seventh	19	3.5
Third	135	24.2	Eighth	6	1.1
Fourth	123	22.0	Sputum entirely absent	61	10.9
Fifth	65	11.6			

siderable proportion of cases—viz., 10.9 per cent.—sputum was never evident, a large percentage in comparison with the cases in which physical signs were absent or rather not detected. Of 100 cases observed by Emerson 16 had no sputum or "very little."²

Herpes.

Herpes labialis—no other situation was observed—was seen in 95 cases—i.e., 17 per cent. Of these only four died (4.2 per cent.), once again confirming the popular impression that the prognosis is more favourable in cases when herpes is present. Geissler³ observed it in 182 out of 421 cases (43.2 per cent.). Osler gives its occurrence as 12 per cent. (40 per cent.).

Termination.

Crisis.—This occurred in 315 cases, including 5 in whom death subsequently took place and 28 who developed empyema. Table VII. illustrates the day upon which crisis occurred, reckoning from the onset of symptoms.

TABLE VII.

Day of crisis.	No. of cases.	Per cent.	Day of crisis.	No. of cases.	Per cent.
Third	25	8.0	Eighth	30	9.5
Fourth	1	2.5	Ninth	16	5.0
Fifth	65	20.6	Later than ninth	22	7.0
Sixth	36	11.4			
Seventh	113	36.0			

I had gained the impression that termination by crisis was relatively less frequent in the Aldershot Command than elsewhere, but my percentage (56.5 per cent.) corresponds very closely to that given (60 per cent.) by Powell and Hartley.⁴ Table VII. confirms the general acceptance that the seventh day is the commonest upon which crisis occurs and the ancient belief that the odd days predominate over the even days. I think it probable that the figures for the seventh day should be augmented at the expense of those given for the sixth and eighth days, as in many of these cases some uncertainty as to the day of onset of the illness was present.

Termination by Lysis.

In this connexion one must, in order to obtain figures for the frequency of lysis in uncomplicated cases, exclude not only the 315 cases in whom crisis occurred, but in addition 56 cases in whom death (antecedent to, or in the absence of, crisis) resulted, 88 cases when empyema developed, and 12 other cases with other complications in whom crisis did not occur. This leaves a residue of 87 cases—that is to say, lysis occurred in 15.6 per cent. cases without complication.

Complications.

Empyema occurred in 116 cases—i.e., 20.8 per cent. This is a proportion considerably larger than the general experience, for of 7394 cases investigated by Hector Mackenzie as regards complications,⁵ empyema was present in only 3.48 per cent. Two circumstances explain the very large percentage in my cases. In the first place, I think there can be no doubt that empyema is relatively a very much more common complication in the Aldershot Command than generally. In the second place, empyema is probably very frequently overlooked because the diagnosis of "unresolved pneumonia" is accepted when physical signs persist in the chest and the patient's general condition does not suggest the presence of pus. Exploration of the chest was a routine proceeding at Aldershot; and whilst no undesirable effects ensued from the operation I am certain that empyema was ascertained and the duration of the illness reduced in many cases in which suspicion of its existence would not have been aroused. Finally, some of the cases included in my series would not be regarded as legitimately empyema in the restricted sense of thick pus (with or without organisms) demanding resection. Of my 116 cases 30 only required resection. In the remaining 86 cases aspiration only on one or two and rarely three occasions was found to be sufficient to cause complete resolution. Such a proceeding naturally cleared up those effusions of a thin serous character containing few pus cells or mononuclears only, but I was certainly surprised at the efficiency of this simple treatment when really thick pus was present, as in the other 60 cases, in 24 of whom

organisms (pneumococci or streptococci) were also identified. Resection was always adopted when it was manifest that extensive drainage was necessary, but I would recapitulate that 86 cases were successfully treated by aspiration alone, of which 26 exhibited thin fluid, usually hæmorrhagic and containing mononuclears and few pus cells; 36 thick pus, in which organisms were not demonstrable; and 24 thick pus, containing pneumococci or streptococci. The average period for complete recovery was so short as compared with that of a resection, even a thoroughly satisfactory one, that I am convinced as to the value of this form of treatment, provided the patient's general condition is carefully watched; and even if resection is regarded as desirable, I believe previous thoracocentesis to be an advantageous preliminary.

Among the 116 cases of empyema 23 deaths occurred—i.e., practically 20 per cent. In the series of 7394 cases already quoted the frequency of empyema is given at 3.48 per cent., with a mortality of 1.12 per cent. Even if one excludes the relatively trivial cases and admits only those with considerable pus formation, the occurrence of empyema in the Aldershot Command must have been relatively very high, at least 14 per cent., and the empyema death-rate then rises to 27 per cent., which approximates to the usual expectation. I must at this point express the conviction that influenza played no part in the production of empyema in this series. When the epidemic occurred the percentage of empyema in pneumonic cases was exceedingly high.

Other Complications.

Meningitis occurred in 6 cases—i.e., approximately 1 per cent. The infection in all was pneumococcal and a fatal result ensued in all. *Meningismus* (i.e., a condition suggesting the possibility of meningitis of some form or other and for which lumbar puncture was performed) occurred in no fewer than 25 cases (i.e., 4.5 per cent.), all of whom recovered.

Pericarditis was discovered in 11 cases only (i.e., 2 per cent.), which is little more than half the percentage given in the big series above referred to and less than half in that of Osler (35 out of 658). Four of the cases died (i.e., 36 per cent.), a much lower figure than that given in Dr. Mackenzie's cases, in which the mortality is just over 70 per cent., and still lower than Osler's 89 per cent.

Infective endocarditis was encountered in 4 cases (0.72 per cent.), which corresponds closely to Dr. Mackenzie's 0.83 per cent.—all 4 cases died.

Of less serious complications or accompaniments *jaundice* was prominent in 7 cases, *arthritis* in 2 cases, *nephritis* in 2 cases, *colitis* in 1 case, and extensive venous *thrombosis* in 1 case. *Delirium* was a very prominent feature in 22 cases (4 per cent.) and 3 cases were actually admitted as cases of acute mania. Among other complications referred to by Dr. Mackenzie, none of which were observed in my series, are peritonitis (0.31 per cent.); otitis media (0.33 per cent.); parotitis (0.05 per cent.); and peripheral neuritis (0.05 per cent.).

Finally, it may be noted that of the 61 deaths 23 occurred in cases with empyema, 6 in cases with meningitis, 4 in cases with pericarditis, and 4 in cases with infective endocarditis. These complications were duplicated on some occasions, so that 28 deaths took place in cases free from any complication.

I am indebted to so many colleagues for their valued assistance that a general expression of gratitude must suffice, but I cannot refrain from a special reference to Dr. Herbert French, late Lieutenant-Colonel, R.A.M.C., and consulting physician to the Aldershot Command, for his generous advice and encouragement and assistance during the greater part of this research.

AN EXPERIMENTAL STUDY ON THE ORIGIN OF IDIOPATHIC NEPHRITIS.*

By H. B. DAY, M.C., M.D. LOND., F.R.C.P. LOND.,

PROFESSOR OF CLINICAL MEDICINE, SCHOOL OF MEDICINE, CAIRO.

With a Note by

J. K. CLARKE, M.B., B.CH., D.P.H.,

LECTURER IN PATHOLOGY, SCHOOL OF MEDICINE, CAIRO.

OUR knowledge of the ætiology of parenchymatous nephritis is largely based on clinical experience. It is a familiar fact that an acute nephritis may arise in the course of many specific infections, and the production of nephritis by various chemical agents has been the subject of numerous experiments. But such modes of origin are notoriously difficult to account for the majority of cases of acute and chronic parenchymatous nephritis admitted to hospital. Hence the designation "Idiopathic Nephritis" still remains as a term of reproach in our text-books.

Bacteriological examination of the urine from cases of acute nephritis has, in the hands of Scheidemandel¹ and others, shown that pyogenic bacteria are occasionally responsible for the disease. In such cases *Staphylococcus aureus*, streptococci, and *Bacillus coli* (the last in insufficient numbers to cause obvious bacilluria) have been obtained on culture of the catheter urine. The causal relationship of these organisms is shown by their disappearance from the urine on recovery of the patients and by confirmatory blood cultures in severe cases. Clinically, the more obviously septic cases are characterised by fever, tenderness in one or both loins, and the appearance of numerous leucocytes in the urine; but in milder forms the picture may be that of a diffuse nephritis.

In chronic cases of parenchymatous nephritis the urine is usually sterile. But in view of the work of Hort,² who employed the urine itself as a culture medium in cases of obscure general infection, I resolved to use incubated urine from a series of cases of nephritis and inject it into animals in the hope of reproducing the disease. At the same time, cultures of this or other material would check any results obtained. This mode of experimentation was based on the assumption that cases of idiopathic nephritis are due to some unrecognised infection of the kidney and that the causative organisms are present with the products of inflammation in the urine and in the kidney itself.

Experiments with Renal Substance.

Soon after the beginning of this investigation I was able to secure a kidney from a patient who had died of acute nephritis complicated by pleurisy with effusion (Case No. 10300). Dr. Yussef Barrada, medical resident at the hospital, had shown a keen interest in the work, and removed the kidney aseptically within two hours of death.

Portions of this organ were at once placed in tubes of sterile liquid serum, while another piece was ground up with normal saline.

Fresh emulsion.—The emulsion in saline was injected into the peritoneal cavity of a guinea-pig. This animal survived, and no albumin could be detected in its urine.

Culture in liquid serum.—These tubes were kept in an incubator for two days and then in a warm room for 15 days. 1 c.cm. of the fluid from one tube was then injected intraperitoneally into guinea-pig (A). The animal died in six days. Autopsy showed effusion into both pleura, and some lymph adhering to the liver and covering the spleen, which was greatly enlarged. The kidneys were congested, and on section showed marked degeneration of the tubular epithelium with casts in situ.

From the organs of the dead pig and from the material injected pure cultures of a very short Gram-negative bacillus were obtained; they were shown to be identical by the sugar reactions.

Subcultures.—From another tube of serum in which a piece of the human kidney had been placed a subculture was made on blood-agar. This showed a growth of the same bacillus described above, with some yeast cells. The growth when a week old was washed off with sterile saline; half was injected into a pig (B), the rest was passed through a Berkefeld filter and at once injected into the peritoneal cavity of another pig (C). Pig (C) injected with the filtrate showed a trace of albumin in its urine, but recovered. Pig (B) showed distinct albuminuria and died in seven days. The

* A paper read at a meeting of the Staff Club, School of Medicine, Cairo.

post-mortem appearances were the same as in pig (A). The kidneys showed an acute hemorrhagic nephritis. Cultures from the heart, blood, and organs recovered the bacilli without yeast cells.

A pure culture was obtained from plating the original subculture and small doses were injected subcutaneously into a white rat and into a guinea-pig. The rat showed distinct albuminuria by the third day, but no albumin could be detected in the alkaline urine of the pig. Both animals were painlessly killed on the fourth day. Agar cultures of the heart blood, kidney, and urine were sterile in each case. Sections of the kidney in both animals showed cloudy swelling of the convoluted tubules with intratubular debris, much hyperemia, and occasional hemorrhages.

Passage.—An agar culture from the kidney of pig (B) was emulsified and injected into two other pigs (D) and (E). Pig (D) was injected intraperitoneally and died the next day. The spleen was very greatly enlarged and the kidneys showed acute degeneration of the tubular epithelium. Pig (E) was injected subcutaneously and died in five days. No albumin could be demonstrated in its urine during life. Post-mortem the spleen was enlarged, but there was no lymph adherent to it or to the liver as in all the other pigs dying after intraperitoneal injection. The kidneys showed a conspicuous degeneration of the tubular epithelium. From both pigs the original bacillus was recovered.

The culture obtained from the original pig used (Pig A) was subcultured four months later and grew well. A guinea-pig was injected subcutaneously with a small dose and was killed a fortnight later. From this pig bouillon cultures were taken of the urine (obtained at autopsy from the bladder) and from three pieces of a kidney. The urine and two of the kidney tubes yielded a pure culture of the bacillus injected; the remaining tube was sterile.

The other kidney and a portion of the liver were sliced and fixed in Zenker's fluid. The kidney on section showed a striking degeneration of the epithelium of the convoluted tubules with casts in situ. The liver changes were remarkable; there was widespread necrosis of the cells and hemorrhages into the liver substance.

Summary.—In this case the features of the disease in the human patient were successfully reproduced in animals. The causative organism was obtained in pure culture and recovered after passage through two sets of animals.

Investigation of Urine.

Material for this work was obtained from 25 consecutive cases of parenchymatous nephritis admitted to my wards. These patients all showed general oedema, often extreme, with albumin and numerous casts in the urine; the more important features of each case are tabulated below. The clinical history elicited was often meagre, but in two cases examination showed that the nephritis was undoubtedly syphilitic in origin. Apart from these two no definite cause for nephritis could be found on examination of the patients.

For the collection of urine from the patients the following technique was finally adopted:—

A sterile rubber catheter was passed with full antiseptic precautions; since male Egyptians are circumcised, one common source of contamination was absent. After some urine had been allowed to escape the catheter was temporarily compressed and its exit end well flamed. Some 10 c.cm. of urine were then collected in a stout sterile test-tube during momentary removal of a sterile rubber stopper. Afterwards the end of the tube and the stopper were again sterilised in the flame. Before the use of rubber stoppers contamination of the urine was liable to occur after some time, but the avoidance of cotton plugs overcame this difficulty. It is advisable to use a couple of tubes for each patient, one for incubation and culture, the other for direct microscopic examination of films prepared from the sediment, both fresh and stained by Gram's method.

According to the results of experiments and bacteriological examination of the urine these cases of nephritis may be arranged in four groups (A, B, C, and D).

Group A.—These urines showed a considerable excess of pus corpuscles (as well as casts), and bacteria were readily found on direct microscopic examination of the fresh deposit.

(a) In the male patients (first 5 cases) this complication was due to a septic cystitis following bilharzial disease of the bladder. In ordinary cases of bilharziasis the discharge of ova gives rise to hæmaturia only, and the urine is sterile. But in long-standing cases a bacterial infection is apt to follow, and often persists after the bilharzial worms have perished. Although a septic extension to the kidneys may terminate such cases, this rarely presents the picture of an ordinary parenchymatous nephritis, and in the examination of over 400 patients suffering from bilharzial disease of the bladder, many of whom had pyuria, I only found one urine containing renal casts, and this man had developed dropsy. Hence, bearing in mind the extraordinary rarity of bilharziasis in Egypt and the comparative rarity of parenchymatous nephritis, there does not appear to be any close relationship between these diseases.

(b) In the three female cases there was no evidence of bilharziasis. One patient (Case No. 10741) had obvious colon bacilluria; in the second (No. 11203) there was a pyuria of doubtful origin (tubercle bacilli not found), while in the third (No. 702) a malignant growth of one kidney was found post mortem. But as all three patients showed the usual symptoms and signs of parenchymatous nephritis they have been included in the list.

Injection of these urines, especially after incubation, was generally fatal to guinea-pigs. The animals succumbed in a few hours to a septicæmia, and from their blood and organs the causative bacteria were recovered. Direct examination of the urinary sediment and of cultures taken showed in most cases a

mixed infection, in which Gram-negative bacilli predominated. Very different types of these organisms were found in the different urines, together with Gram-positive bacilli and cocci in some instances.

Group B.—These cases of nephritis were complicated by urinary bilharziasis, but without signs of any septic infection. The urine contained abundant casts, some blood corpuscles, and bilharzia ova more or less embedded in cells, chiefly eosinophiles. The fresh urine was sterile and appeared innocuous on injection into the peritoneal cavity of a guinea-pig. But after a short period of

incubation the urine of the first two cases showed a growth of Gram-negative bacilli, and killed guinea-pigs in six hours with a dose of 3 c.cm. From the last two cases in this group Gram-positive bacilli were isolated, but grew feebly on agar.

Group C.—These urines showed no signs of any complicating disease of the urinary tract. Cultures taken from the fresh catheter urine were often sterile, but after the urine had been incubated for one day or longer a positive result was obtained. In all these cases the cultures showed a pure growth of short bacilli, Gram-negative and aerobic. Animals which died as the result of infection or had been purposely killed to ascertain the effect were found to have developed a distinct nephritis.

Group D.—The urines in this group were free of all signs of complicating disease. They were sterile on culture and remained sterile for weeks on incubation. Three urines which had remained sterile on incubation were tested for their toxic effect. The urine was injected subcutaneously into a guinea-pig which was killed after a week and the organs at once fixed in Zenker's fluid for microscopic study. Case 4107: This urine was obtained from a case of subacute or chronic nephritis and contained 3 parts per 1000 albumin. A guinea-pig injected with 3 c.cm. incubated urine was killed ten days later. The liver and kidneys were normal on careful microscopic scrutiny. Case 3079: This urine resembled serum in appearance; it had a sp. gr. 1036 and contained at least 31 parts per 1000 protein (globulin being present). The patient had more or less oedema for three years and gave a positive Wassermann reaction. A guinea-pig was injected with 3 c.cm. and killed ten days later. Its liver showed areas of focal necrosis with hemorrhages; the kidney some cloudy swelling and a few hemorrhages. Case 1814: The fresh urine from this case of acute nephritis (Group C) was doubly filtered through a Berkefeld candle and remained sterile on incubation. 2½ c.cm. was injected into a guinea-pig and the animal killed seven days afterwards. Microscopic examination of the liver showed a normal appearance; the kidneys were also normal except for a very slight cloudy swelling in a few of the renal tubules.

Summary.—The toxic effect of nephritic urine was shown to depend chiefly on the presence or absence of bacteria. In view of the precautions taken in the collection of the specimens and the absence of the usual contaminating organisms such as cocci and yeasts, the frequency with which pure cultures of Gram-negative bacilli had been obtained was significant. Further, these results corroborated those obtained from the experiments with actual kidney tissue already detailed, and indicated that further study of the bacilli isolated was necessary.

The Characteristic Organism.

The bacteriological part of this investigation was kindly undertaken by Dr. J. K. Clarke, who reports as follows.

Note by Dr. J. K. CLARKE.

"The organisms are all short, plump, Gram-negative bacilli, and their cultural characteristics are those of the coli-typhoid group. Some are motile, some non-motile; some produce indol from peptone water, others do not; and they differ in power of fermenting carbohydrates. The following are the reactions which they give:—

Case No.	Motility.	Glucose.	Lactose.	Dulcitol.	Saccharose.	Mannite.	Maltose.	Indol.
11082	0	AG	AG	AG	AG	AG	AG	+
11203	0	AG	AG	AG	AG	AG	AG	+
599	+	AG	AG	AG	AG	AG	AG	+
10741	+	AG	AG	AG	AG	AG	AG	+
7286	+	AG	AG	AG	AG	AG	AG	+
10821	+	AG	AG	AG	AG	AG	AG	+
702	+	A	—	A	—	A	A	+
10300	+	AG	—	AG	—	AG	AG	0
2021	+	AG	—	AG	—	AG	AG	0
5170	+	AG	—	AG	—	AG	AG	0
1814	+	A	—	—	—	A	A	0
1946	+	AG	—	—	—	AG	AG	0

A, acid formation; G, gas production.

As will be seen, the first five are lactose fermenters, 10741 and 7286 giving the reactions of *B. coli communis* and the others being closely allied. 10300, 2021, and 5170 appear to belong to the paratyphoid-Gärtner subgroup. 1814 and 1946 grew very slowly, in contrast to the remainder, whose growth was vigorous, and 1946 fermented glucose, mannite, and maltose only feebly. Another organism (No. 2149) could not be grown in subculture.

Agglutinating sera for the most important of the organisms are being prepared, and when these are ready further experiments will be carried out with a view to a more definite classification."

Injection of Cultures into Animals.

The relation of these organisms to nephritis was tested in two ways: (1) by injection of pure living cultures into animals; (2) by the use of killed cultures as vaccines for treatment of cases of nephritis in man.

Injection of cultures.—In planning these experiments advantage was taken of the results of previous experiments to avoid sources of error. Thus, it had been found that incubated urine and cultures of the organisms in fluid media were often toxic enough to kill guinea-pigs on intraperitoneal injection in comparatively small doses. The animal succumbed to a general septicæmia, and it was quite possible that the nephritis induced was due rather to a profound toxæmia than to a selective action on the kidneys. Hence, quite small doses of an agar culture emulsified in saline were preferable; the injections should be subcutaneous where any local irritant effect could be observed.

Secondly, it was obvious that the urine of guinea-pigs was quite an untrustworthy indicator of any nephritis present. The urine of these animals is so highly alkaline that tests for albumin were generally negative, even when an advanced degree of renal disease was undoubtedly present. So it was resolved to use white rats for preference, since these animals excrete an acid urine normally free from albumin.

Lastly, the experimental animals were to be killed at definite intervals, cultures taken, and specimens for microscopical study preserved in Zenker's fluid to obtain the best results.

For these experiments pure cultures from uncomplicated cases of nephritis were selected (Cases No. 1814, 1946, 2021, and 11082).

No. 1814.—This bacillus was obtained in pure culture from the urine of a boy ill with acute nephritis. Two rats (A) and (C) were each injected with 1.5 c.cm. of a fairly strong emulsion made from a subculture; a third rat (B) was injected with 1 c.cm. of sedimented urine after incubation.

All three rats developed an albuminuria within three days, and this persisted until they were killed after varying periods. At first the rats appeared somewhat ill and excreted little urine; later they showed no obvious symptoms. The albumin, precipitated by boiling, occupied from 1/10 to 1/6 of the volume of urine. Some pus corpuscles were present, but casts could not be identified. There was no swelling at the sites of inoculation.

Rat (A) was killed one week after injection. Agar cultures of the heart blood, spleen, and kidney remained sterile. The spleen was greatly enlarged, measuring 1½ in. in length. On section the kidney showed definite hyperæmia and marked granular degeneration of the epithelial cells of the convoluted tubules, the changes being of wide but unequal distribution. The spleen showed a general hyperplasia.

Rat (B), injected with incubated urine, was killed after an interval of two weeks. As before, agar cultures of the blood and kidney remained sterile; the spleen measured 1 in. in length. On section the kidney showed marked hyperæmia with actual hæmorrhages into some tubules and glomeruli. There was widespread degeneration of the tubular epithelium, and a few glomeruli showed proliferation of the cells lining Bowman's capsule. In places a small-celled infiltration was seen between the tubules.

Rat (C) was killed six weeks after injection of the culture; it had shown persistent albuminuria. Cultures were negative; the spleen measured 1½ inches in length. On section of the kidney there was definite degeneration of the renal epithelium, affecting chiefly the convoluted tubules, with areas of well-marked infiltration of cells, more numerous in the cortex.

No. 1946.—This culture was obtained from a patient who had had nephritis for some ten weeks. 1.5 c.cm. of a fairly thick emulsion was injected subcutaneously into a rat. The animal developed an albuminuria, slight at first, but quite definite after ten days. It was killed five weeks after inoculation, and at this time blood corpuscles and leucocytes were found in its urine. On section the kidney showed hyperæmia with hæmorrhages between the tubules and into some glomeruli. The renal epithelium was degenerated, especially in the convoluted tubules; there was some proliferation of the capsular epithelium in certain glomeruli, and in places a small-celled infiltration.

No. 2021.—This culture was obtained from a case of nephritis of two months' duration; the patient had suffered from malaria, and had a typical attack while in hospital. 2 c.cm. of a thin emulsion of the culture were injected subcutaneously into a rat. Here, again, there was no local reaction, and it was some ten days before albumin was unmistakably present in the urine. The albuminuria, however, persisted until the animal was killed, six weeks later. At autopsy the spleen measured 1½ inches in length. The kidneys showed less epithelial degeneration than in the preceding animals, and there were no hæmorrhages, but a small-celled infiltration was evident in many parts of the cortex.

No. 11082.—This organism was obtained from the urine of a resolving case of acute nephritis. The urine contained some pus, but showed no evident bacteria. Cultures taken from a fresh catheter specimen were sterile, but after incubating the urine for 24 hours a positive result was obtained. 3 c.cm. of this incubated urine in an early experiment had been injected into the peritoneal cavity of a guinea-pig. The animal died in six hours, and from its heart's blood the original bacillus was recovered. Later the culture obtained on passage was subcultured and a loopful emulsified and injected subcutaneously into another pig. This animal was killed after seven days and bouillon cultures taken of its blood, urine, and kidney. The cultures remained sterile. On section the kidney showed degeneration of the epithelium of the convoluted tubules, very marked in places, with tube casts in situ and occasional hæmorrhages. The liver showed profound degeneration—almost necrosis of many cells, especially at the centres of the lobules.

Two other guinea-pigs were injected with very small doses of a subculture of the original obtained from the patient's urine. One was killed a fortnight later and showed moderate degeneration of the cortical epithelium with a few hæmorrhages; cultures remained sterile. The second pig was killed after an interval of three weeks, and the results were similar. In this pig the liver was examined and showed very distinct degeneration of the cells.

Summary.—The results of these experiments with pure cultures of bacilli isolated from uncomplicated cases of nephritis may be summarised as follows:—

(a) General effects. Moderate doses did not produce a fatal septicæmia, but there was a well-marked swelling of the spleen which persisted for some time after the blood-stream was free of bacteria. This phenomenon, it may be remarked, is seen in cases of human typhoid, and a similar enlargement of the spleen has been reported in epidemic nephritis in civil life.

(b) Nephritis. The nephritis induced ran a distinct course which varied in intensity according to the virulence of the strain and amount of the culture injected. The chief changes were: An early hyperæmia with degeneration of the renal epithelium, most marked in the convoluted tubules. Later, more advanced degeneration with continued hyperæmia and hæmorrhages into the tubules and occasionally the glomeruli. Casts could be seen in situ. Lastly, some proliferation of the interstitial tissue. In no case did the nephritis show the characters of a septic infection. There were no intense glomerular changes nor leucocytic infiltrations.

(c) Liver changes. In the animals examined for such changes it was found that the bacilli had quite as marked an effect on the liver as on the kidneys. There was profound degeneration, amounting sometimes to actual necrosis, with hæmorrhages.

An interesting feature was the persistence of the renal lesions for weeks after no organisms could be detected on culture of the organ in animals killed at an earlier stage.

Experiments with Other Organisms.

In light of the knowledge gained of the effects of these bacilli obtained from cases of uncomplicated nephritis it was possible to apply the experimental test to other organisms isolated from cases where a secondary infection could not be excluded. This would also afford an opportunity to correlate the effects produced on the kidneys and the liver. For this purpose pure cultures of strains whose characters had been ascertained already were used. The same procedure was followed as in the first series, using the following organisms: (1) Intestinal types, Nos. 10741, 7286, 702, 11203, and 10821; (2) Gram-positive bacilli, Nos. 2136 and 3360.

In each series the animals were inoculated subcutaneously with approximately similar doses and killed at the end of a fortnight. In no case was there any noticeable reaction at the site of injection.

CHART 1.—Case 8934. Chart from ninth week of stay in hospital. The thick continuous line shows the daily excretion of urine; the thin interrupted line the amount of albuminuria. A, Autogenous vaccine No. 1, dose 40 millions; B, 60 millions; C, 100 millions. D, Autogenous vaccine No. 2, dose 20 millions; E, 30 millions. F, Vaccine from Case 11082, dose 25 millions; G, 50 millions; H, 75 millions.

(1) The Gram-negative series showed a very interesting gradation of effect on the kidneys and liver, ranging from the slightest disturbance to an extremely severe lesion.

Organism No. 10741 gave the typical cultural characteristics of *Bacillus coli communis*. The pig injected with an emulsion and killed a fortnight later showed a normal liver and practically a normal kidney. This result was confirmed by an experiment on a rat which was injected with rather a large dose of a *B. coli* culture obtained from a case of simple bacilluria. The animal died in two days and the kidneys showed some hemorrhages, but the renal cells showed little signs of degeneration.

Organism No. 7286 had a slight but distinct effect. The liver exhibited degeneration of scattered cells and the kidney showed some hemorrhages and degeneration of the epithelium in various tubules.

Organisms Nos. 702 and 11203 showed a more powerful toxic effect. There was a diffuse degeneration of the epithelium in most of the renal tubules, especially in the cortex, with occasional hemorrhages. The livers showed degeneration of many cells, with badly-staining nuclei, while the liver of the pig injected with No. 702 was studded with numerous hemorrhages.

Organism No. 10821 had a profoundly toxic effect. The liver showed absolute necrosis with loss of cell outline and nuclei. In the kidneys the epithelium of tubules both in the cortex and medulla were highly degenerated with casts in situ and hemorrhages.

A rat injected with the same culture was killed 30 days later. The liver exhibited distinct degeneration, while the kidneys showed a good deal of tubular degeneration with hemorrhages. During life there was albumin present in the rat's urine.

(2) The Gram-positive bacilli isolated from cases Nos. 2136 and 3360 had little similar effect. A rat injected with organism 3360 failed to develop albuminuria. A pig killed a fortnight after inoculation with organism No. 2136 showed very slight degeneration in some of the renal tubules, but some excess of connective tissue. The liver of this animal exhibited a very distinct degree of early fibrosis; the hepatic cells were healthy.

Remarks.—The experiments showed that organisms of strictly *B. coli* type had little effect, while other strains which appeared closely related might cause severe degeneration of the kidneys and liver. In all cases the effect on these two organs was closely comparable.

Trial of Vaccines.

The ætiological significance of the cultures obtained from incubated urine in cases of nephritis was tested by their use as vaccines for patients. The following case-histories and charts illustrate the effects produced:—

CASE 8934.—A male of 31 years was admitted in October, 1919, for general oedema and scanty urine of three weeks' duration; there was no history of preceding illness. Examination showed extensive oedema with ascites and a right hydrothorax. The urine averaged 400 c.c. per diem; it had a sp. gr. 1028, was acid in reaction, and contained 15 parts per 1000 albumin. The sediment showed abundant casts, many pus cells, and large non-motile bacilli. Injection of this urine was quickly fatal to guinea-pigs.

The patient was placed on the ordinary treatment and his abdomen tapped. During the first month he improved slightly, the amount of urine rising to a daily average of 1000 c.c. His condition then remained stationary for the next two and a half months (vide Chart 1); the oedema persisted with the same urinary output and an albuminuria of 12 to 16 parts per 1000 (Esbach). Examination of the blood showed no retention of urea.

A vaccine was prepared with considerable difficulty. The large bacilli observed grew unchanged in incubated urine, but on agar lost their staining powers very rapidly. Injections of this vaccine reduced the amount of pus in the urine to a sensible extent, but had no effect on the nephritis beyond reducing the degree of albuminuria to about 12 parts per 1000. The general oedema and quantity of urine excreted were unchanged.

Trial was therefore made of a vaccine prepared from a culture obtained from a case of resolving nephritis in hospital. (No. 11082.) The effect of the first dose of 25 millions was slight, but a second injection of 50 millions was followed by a marked diuresis which persisted until his discharge five weeks later. In the first ten days of this diuresis he lost 21 lb. weight with a rapid disappearance of his ascites and oedema, while the albuminuria fell to the low level of 1.5 parts per 1000. This striking result was closely similar to that reported in a case of syphilitic nephritis under specific treatment about this time.⁵ (No. 10774.)

It appears, therefore, that the bacilli so evident in this patient's urine represented an independent infection and had no causal relation to his nephritis. The success of a vaccine prepared from another case of nephritis indicated that there was another bacillus infecting the kidneys allied to this 11082 organism.

CASE 1814.—A boy of 6 years was admitted with ascites and marked dropsy, stated to have been present for ten days only. The heart was slightly dilated, there was some bronchitis and irregular fever. Both the liver and spleen showed a minor degree of chronic enlargement, probably due to Banti's disease, which is very common in Egypt. The boy showed no signs of congenital syphilis. The urine averaged 250 c.c. per diem; sp. gr. 1020 with 2 parts per 1000 of albumin. Microscopically many casts—blood and cellular—were found with a few bilharzia ova.

On the seventh day after admission he was given a small dose of the 11082 vaccine (10 millions). This was at once followed by an increased output of urine (vide Chart 2), but the diuresis was not

CHART 2.—Case 1814. A, Vaccine from Case 11082, dose 10 millions; B, 12 millions. C, Autogenous vaccine, dose 15 millions; D, 30 millions.

maintained and the oedema showed no sensible diminution in spite of a second dose. Meantime a vaccine had been prepared from a bacillus grown in pure culture from a catheter specimen of his urine of a different type to the 11082 organism. Injection of this autogenous vaccine led to a very rapid disappearance of the extensive oedema and ascites with a loss of 1 lb. in weight. Convalescence was interrupted by a bout of fever for a few days, but was extremely rapid, and he was discharged with urine perfectly free from albumin.

CASE 2021.—A man, aged 25, was admitted for general oedema, which had come on gradually after an attack of fever two months before. His subsequent history shows that this fever was probably malaria. On examination the patient was anemic (haemoglobin 50 per cent.); the spleen was palpable and ankylostoma ova were found in his stools. The urine averaged 1000 c.c. daily, had a sp. gr. 1015, and contained 1 part per 1000 albumin. Microscopically there was an extraordinary number of casts, but no excess of pus corpuscles. He was given oil of chenopodium and received a dose of the 11082 vaccine (50 millions), but then developed intermittent fever. This was found to be malarial and yielded to quinine. Neither the vaccine nor thorough quinine therapy had any effect on the nephritis.

Meantime a culture had been secured from the catheter urine, before the onset of fever, and as soon as the temperature had

settled a small dose of autogenous vaccine (25 millions) was given, but without result (vide Chart 3). Nine days later a larger dose of 100 millions was injected and was immediately provocative of an unmistakable diuresis. Unfortunately, the patient had developed a troublesome diarrhoea, and insisted on his discharge rather than submit to a restricted diet.

CHART 3.—Case 2021. A, Vaccine from Case 11082, dose 50 millions. B, Autogenous vaccine, dose 25 millions; C, 100 millions.

Of course one case proves nothing, but the course of the nephritis in this patient shows that it can hardly have been malarial in origin, and I confess to being somewhat sceptical of the large rôle assigned to this fever in the ætiology of nephritis in warm countries.

CASE 4397.—A man, aged 24, was admitted for general oedema and breathlessness of gradual onset for the past four months. The swelling had first appeared in the eyelids, then in the scrotum and abdomen, and last in the limbs. On admission there was ascites and the heart was dilated and irregular without murmurs; the blood pressure was unusually low (systolic 97 mm.; diastolic 74). The urine was of high sp. gr. and contained a fair trace of albumin; the daily amount excreted is shown in Chart 4. Microscopically, numerous granular casts were found; cultures were sterile.

CHART 4.—Case 4397. The continuous line shows the daily excretion of urine; the interrupted line shows the variations in the ascites recorded by measurement of the abdominal circumference. T, Abdomen tapped (8000 c.cm.); T', Second tapping (8500 c.cm.). A, Vaccine from Case 11082, dose 50 millions; B, 100 millions. C, Vaccine from Case 1814, dose 50 millions; D, 80 millions; E, 120 millions.

The patient failed to improve after admission to the wards. His abdomen was tapped and 8 litres withdrawn, but the fluid at once began to reaccumulate, in spite of treatment with digitalin and saline purgatives. Two doses of the 11082 vaccine were administered, but the output of urine fell rather than increased, and the ascites had to be tapped again. Since the temperature had been slightly irregular the possibility of septic endocarditis was considered, but a leucocyte count was normal (8150).

Finally, trial was made of the 1814 vaccine, and the patient immediately responded. In spite of the heat of an Egyptian summer there was a decided diuresis, and the tide of accumulating ascitic fluid was turned. As in the other cases there was no rise of blood pressure, but the heart became regular and smaller in size. The granular casts practically disappeared from the urine, and the patient made a rapid recovery from his very serious condition.

The special interest in this case lies in the effect of one particular vaccine on a case of chronic nephritis with dilated heart, when the urine was sterile. A similar result was obtained in another patient with marked oliguria and dropsy, but without any sign of heart failure and only occasional albuminuria.

Control cases.—To check these results trial was made of these vaccines for cases of chronic cardiac disease and of hepatic cirrhosis with ascites, but in no instance was any diuretic or other effect observed. A vaccine prepared from a Gram-positive bacillus (Case 3360) had no effect on the nephritis of this patient.

Remarks.—The above examples show that the effect of vaccines is specific, and is only obtained when a suitable strain of organism is used. The reaction is usually immediate, but may occur after

two or three days' interval. Naturally a great deal more work requires to be done before the best methods of using vaccines can be evolved. But it can be stated that the use of autogenous vaccines is generally indicated since the strains of bacilli isolated show decided differences. Such vaccines, however, may fail in cases complicated by some other infection of the urinary tract, for they may contain few organisms derived from the kidneys. Dr. Clarke has tried plating such cultures on McConkey's medium so as to isolate bacilli of intestinal type. For early use in such cases, and for patients in whom the acute stage is passed and the urine may remain sterile on incubation, stock vaccines are of value. It is proposed to try large doses of detoxicated vaccine made by pooling vaccines prepared from the various strains already isolated and others doubtless to be found in the future.

Discussion of Results.

These investigations indicate that many cases of "idiopathic" nephritis—acute, subacute, or chronic—may be due to infection by bacilli of intestinal types. In its mode of origin the affection would therefore be akin to colon bacilluria, but the particular germs responsible attack the renal epithelium and not the urinary tract. The type of lesion reproduced experimentally is essentially a tubular nephritis. The severe forms of glomerulo-nephritis seen in some specific fevers and septic infections appear often due to pyogenic bacteria (especially streptococci) or other organisms responsible for a septicæmia. But while the bacillary form described in this paper never appears to present the features of a septic nephritis, it can cause hæmorrhage from the kidney.

It is well known that a nephritis once established has a strong tendency to become chronic. The nephritis induced by injection of the bacilli isolated exhibited a similar tendency, although it was rarely possible to recover the germs from the animals infected when the early stage was past. This fact may explain why the urine from cases of chronic parenchymatous nephritis in man is so often sterile. In such cases the acute stage of the infection has passed leaving the kidney severely damaged, its powers of recovery possibly jeopardised by injudicious feeding before the nature of the disease was apparent. The work of Allen on experimental diabetes has shown that, in a dog whose pancreas has been reduced to a minimum, a fatal progressive diabetes may be induced or avoided according to the diet given. Recovery from acute nephritis is probably largely influenced by a suitable diet. On the other hand, in chronic cases a vicious circle may follow the excessive loss of serum albumin in the urine. Hence we should always expect to find germs in the urine of acute nephritis (apart from cases of poisoning), but not necessarily in the chronic stages.

Following the work of Opie and Oertel on the changes produced in the liver as well as in the kidney by the chemical excitants of nephritis, in my later experiments I found the same to hold true of bacillary nephritis. Although this result may seem at variance with our ideas of nephritis it is not opposed to clinical experience. For in the two diseases of man which are invariably associated with nephritis—i.e., eclampsia and infectious jaundice (spirochaetosis ictero-hæmorrhagica)—the changes in the liver are notoriously as important as those in the kidneys. And it is an aphorism that in febrile cases with jaundice the urine is albuminous, an observation which illustrates the close relation between these organs both in function and liability to disease.

On this point, as indeed on the others raised, much work remains to be done. But the probability of hepatic lesions being coincident with the renal changes in parenchymatous nephritis should be taken in account in investigating the metabolic disturbances that occur in the disease. It is possible, for instance, that a non-retention of urea may partly depend on a defective formation of this substance by a diseased liver.

Summary.

(a) From the urine of patients with "idiopathic" nephritis and from the kidney of a case of fatal nephritis,

bacilli of intestinal types have been isolated in pure culture.

(b) Injection of these cultures and subcultures into animals provokes an acute nephritis.

(c) From the kidneys of these animals in the earlier stages of nephritis the bacilli injected have been recovered in pure culture.

(d) Injections of cultures obtained from animals infected with these bacilli have reproduced the disease in other animals.

(e) The nephritis induced runs a somewhat prolonged course, and is accompanied by acute degeneration of liver cells and an enlargement of the spleen in the early stage.

(f) In human cases of nephritis treatment with appropriate vaccines has caused rapid amelioration.

(g) In some cases of nephritis a secondary or an independent infection of the urinary system may be present and obscure the original cause. This complication is probably more common in Egypt than elsewhere owing to the prevalence of bilharziasis.

In conclusion, it is my pleasant duty to record the valued help of my friend Dr. Clarke, who is responsible for the bacteriological classification and has done much to help the research. My thanks are similarly due to Dr. Yussef Barrada, who secured so many cases of nephritis for my section, and to my house physicians for their care of the patients, collection of urine, and injection of vaccine.

THE USELESSNESS OF ANTIMONY IN THE TREATMENT OF FILARIASIS.

BY GEORGE C. LOW, M.A., M.D., M.R.C.P.,

SENIOR PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES, ENDSLEIGH GARDENS, N.W., AND SEAMEN'S HOSPITAL, ROYAL ALBERT DOCK, E.; LECTURER AND CONSULTING PATHOLOGIST TO THE LONDON SCHOOL OF TROPICAL MEDICINE, ETC.;

AND

A. L. GREGG, M.D., B.Ch., B.A.O.,

MEDICAL SUPERINTENDENT, HOSPITAL FOR TROPICAL DISEASES, ENDSLEIGH GARDENS, N.W.

Sir Leonard Rogers¹ has recently reported some observations upon antimony injections given intravenously for the treatment of filariasis, and has pointed out that very careful and prolonged counts are necessary before coming to a conclusion as to the efficacy of this treatment. His results, on the whole, appear to indicate that these injections have a definite effect in greatly reducing the filarial embryos or causing them to disappear from the peripheral blood, presumably as a result of the destruction of the adult worms.

Recital of a Case.

One of us (G. C. L.) has recently pointed out that for all filarial work, such as estimating embryos, it is essential that measured quantities of blood should be taken, and that before any treatment is commenced the number of embryos occurring regularly in the blood should be known accurately. Variations are not uncommon, and may give rise to false impressions. The drug may act either by killing the embryos or by killing the adults or by killing both. Having had the opportunity of studying a case of filariasis (*F. bancrofti* infection), with plenty of embryos present in the night blood, we gave the patient a series of tartar emetic injections intravenously, and controlled these by nightly examinations of the blood, both before, during, and after the injections, the same measured quantity of blood (20 c.mm.) being taken at the same hour nightly. Dried films were made, the haemoglobin then being washed out and the film stained with fuchsin. For the determination of death of the embryos wet cover-glass preparations were also employed.

History of the case.—Mr. V., a native of India, had lived there all his life till he came to England in July, 1919.

Previous illnesses.—No dysentery, no malaria, no venereal disease.

Present illness.—This began with an abscess on the inner side of the left thigh over the adductor tubercle ten years ago. *F. bancrofti* embryos were found in his night blood then. Six years ago he had another abscess, this time in the left groin; it was deep and was operated on and drained. In 1914 an abscess developed in the scrotum. After that the scrotum began to enlarge, the enlargement being of an intermittent nature and sometimes disappearing entirely. The attacks of enlargement were accompanied by pain, fever, and general malaise. Finally, the condition passed into a permanent one and definite elephantiasis supervened. The patient saw Sir James Cantlie on coming to London in 1919. The latter operated upon him, removing the elephantoid scrotum with successful results. Since then the patient has been living in England and has suffered from no further febrile attacks.

Examination.—Teeth had all been taken out for pyorrhoea. Heart and lungs normal. Urine: No albumin, blood, or sugar.

Filarial condition.—Has had an elephantiasis of scrotum, successfully operated on. Penis also slightly affected. Deep scar in left groin, also another on inner side of left thigh. Glands enlarged just below Poupart's ligament on left side. Elsewhere no enlargement.

Blood.—A fair number of *Filaria bancrofti* embryos in night blood; definite nocturnal periodicity.

Injections and Filarial Counts.

Tartar emetic injections were given intravenously in the usual manner, commencing with $\frac{1}{2}$ gr. and increasing by a $\frac{1}{2}$ gr. each time till $2\frac{1}{2}$ gr. was reached, a total of $17\frac{1}{2}$ gr. in all being given. The patient bore these very well without ill-effects.

The following table gives the details of the filarial counts and the injections:—

(A) Number of filarial embryos in 20 c.mm. blood.
(B) Number of grains of A.T. injected.

* It was decided at this date to stop the injections as they were doing no good.

Discussion of Results.

A perusal of the above table shows that the injections, consisting of a total of $17\frac{1}{2}$ gr. of tartar emetic, had no effect upon the infection at all, the adult worms not being killed and going on pouring embryos into the blood as before. The embryos were not all killed either as, even though reduced in numbers as on the night after the injections, those present were alive and healthy.

The only feature worthy of note is, that at first there were fewer embryos in the sample of blood taken on the night of the injections which were given at 4 P.M. This is not surprising when one considers that they would be in the lungs at that time and that the antimony would come in direct contact with them in a concentrated solution. That there was no effect upon the adults is shown by the numbers being up to normal the next evening and afterwards. Further, towards the end of the injections, even although the large dose of $2\frac{1}{2}$ gr. was being given, this temporary disappearance was no longer noticeable, the number found on the same evening as the injections being up to the average, or even a little above. The table illustrates also the considerable constancy, in this individual case, of the number of embryos in the blood every evening. If the female worms constantly pour young into the blood, then there must be a corresponding destruction going on, to keep the numbers at this mean rate. Possibly on the days when over 20

¹ THE LANCET, 1919, ii., 604; Brit. Med. Jour., May 1st, 1920.

embryos per slide were found there may have been an increased out-pouring from the female; or, of course, there may have been several females present giving birth to embryos intermittently.

It would appear, therefore, that antimony is not to prove a specific for filariasis as it is for bilharzial infections, but the only way finally to decide this point is to follow up cases, as has been done above, all results being checked by careful enumerations of the embryos. We have to thank Sir James Cantlie for letting us test the efficacy of the injections in this case.

NOTES ON THE TREATMENT OF RECURRENT MALARIA BY NOVARSNOBENZOL.

BY J. NORCOTT D'ESTERRE, L.R.C.P. LOND.,
LATE MEDICAL OFFICER, THIRD LONDON GENERAL HOSPITAL,
WANDSWORTH, S.W.

So much has already been written as to the nature of malaria, the clinical and other characters of the disease, and the lines of treatment found to be most successful, that I propose here only to touch on a series of cases of recurrent malaria treated by me at the 3rd London General Hospital, Wandsworth, by intramuscular injections of novarsnobenzol (neokharsivan). Having seen during the last three years at least 500 cases of recurrent malaria from all parts of the world, I was struck by the fact that in all these cases the usual varieties of routine quinine treatment (i.e., by the mouth, intramuscular and intravenous) had been tried, in many cases pushed so far as to produce temporary blindness and deafness, and yet upon arrival in England the patients were still suffering from the disease, as shown by blood smears and a differential count. I therefore decided to venture on another line of treatment.

Rationale of Treatment.

My reasons for using novarsnobenzol were:

1. Because it has been conclusively proved that the malarial fevers are protozoal infections, infecting the red corpuscles of mammals, reptiles, and birds.
2. Because the organic compounds of arsenic in its trivalent form are more potent in action upon protozoa.
3. Because it is known to destroy the *Spirocheta pallida*, the balance of opinion now being distinctly in favour of the *Spirocheta pallida* being a protozoon.¹

The reason why the spirochaetes vanish so quickly after salvarsan, or neokharsivan, is that they contain free OH groups, since in their colloidal lipid membrane an unsaturated fatty acid exists. It is to these OH groups that the metals become attached, with the result that the organisms perish. I therefore hoped the same result might take place with the malarial parasite.

The preparation used was novarsnobenzol (B. W. and Co.), which is easily soluble in water, yielding a neutral solution suitable for intramuscular or intravenous injection. The first two injections consisted of 0.3 g. in 5 c.cm. 0.5 per cent. sterile saline, and the last two injections of 0.4 g. in 7 c.cm. 0.5 per cent. sterile saline. These injections are given at intervals of one week. A line is drawn backwards from the anterior superior iliac spine to the top of the natal fold; this line is divided into three equal parts; the point of intersection of the upper and middle third is the site of injection. All the usual antiseptic precautions should be taken with regard to the sterilisation of needles and syringe. The night before treatment the patient is given a laxative, the following morning, three hours before the injection, he is given a light breakfast, and the food on that day should be light so as to throw as little strain as possible on the digestive organs during the elimination of arsenic. The patient should stay in bed for at least three hours after the injection, and in order to prevent any after-pains or reactive painful infiltration hydropathic measures such as moist compresses, hip-baths, or the application of a hot-water bottle may be employed.

If the pain is very severe I give the following powder, which I find efficacious: Pyramidon, 10 gr.; medinal, 3 gr.; heroin hydrochlor., 1/12 gr. In between the injections he is kept on mist. malaria (contains 2½ gr. quin.).

In all cases an examination of the blood is made before each injection with regard to the presence of the malarial parasite, and a differential blood count to ascertain especially any increase of the large mononuclears. This is a very important feature, as in cases where the parasite cannot be demonstrated in the blood the mononuclear reaction, along with the presence of pigment in the mononuclear cells (due to phagocytosis of pigment formed by the parasites), has been taken as evidence that the case is one of malaria. The mononuclear reaction is especially interesting from the fact that in other protozoal diseases an activity of the same elements has been observed.

Notes on Cases.

The following cases were all treated by intramuscular injections.

CASE 1.—Capt. E., R.A.M.C.(T.), the first patient of the series, was suffering from malignant malaria, contracted in Palestine, which produced pyrexial relapses every fortnight in spite of 14 intramuscular injections of quinine, and 45 gr. or more by the mouth daily for a month, followed by 30 gr. for three months. The cachexia, anaemia, and myocarditis served to emphasise the inadequacy of quinine. The effect of neokharsivan injections was to extend the fortnightly periodicity of relapses to an interval of two months in the first series, and to six months for the second series of injections.

Treatment started on May 19th, 1919. Patient left hospital on Sept. 19th, 1919; reported no lapse in December, 1919, and up to date (July, 1920) reports no recurrence. This patient had four intramuscular injections and one intravenous. He was hypersensitive to arsenic and developed a rash and acute asthmatic symptoms.

CASE 2.—Lieut. B., age 36. Type, M.T. Previous attacks 21. Five injections from July 24th to August 25th, 1919. Left hospital well. Reported Oct. 29th, 1919. No relapse.

CASE 3.—Lieut. P. Type B.T. Four injections. No malaria parasites present upon discharge. An acute attack of exfoliative dermatitis after last injection.

CASE 4.—Lieut. E. Type B.T. Sept. 18th, 1919, four injections. Left hospital Dec. 19th quite well.

CASE 5.—Capt. S. Type B.T. Four injections Sept. 18th, 1919. Left hospital Dec. 19th, 1919, quite well. Reported Feb. 7th, 1920. No relapse.

CASE 6.—Lieut. L. Type B.T. Five injections. Discharged quite well Oct. 5th, 1919.

CASE 7.—Lieut. A. Type M.T. Ten previous attacks occurring every two weeks. Four injections. Discharged quite well, December 1919. First injection Oct. 14th, 1919. Reported hospital Feb. 26th 1920. Very well. No relapse.

CASE 8.—Capt. M., R.A.M.C. Type M.T. Four injections. Discharged quite well Oct. 8th, 1919.

CASE 9.—Lieut. B. Oct. 31st. Type M.T., contracted in Macedonia. Fifty-four attacks. Spleen enlarged, tender. Four injections. Left quite free Dec. 20th, 1919.

CASE 10.—Lieut. B. Type B.T. First injection, Nov. 11th, 1919; fourth injection, Dec. 3rd, 1919. Left hospital free. Reported hospital March 25th, 1920. No attacks for over four months.

CASE 11.—Lieut. D., R.A.F. Type B.T. Four injections. Left hospital Feb. 25th, 1920, quite well. Seen in June, 1920. No recurrence.

CASE 12.—Lieut. W., R.A.F. Type B.T. First attack in Persia, 1916; since 14. Completed course, four injections. Discharged quite well Jan. 19th, 1920.

CASE 13.—Lieut. J., 31st Punjab. Type B.T. First attack India, 1916; since ten. Four injections December, 1919. Patho. logical laboratory report: No parasites present.

CASE 14.—Lieut. F., R.F.A. Type B.T. First attack Batoum, 1919; since 3. November, 1919, four injections. Discharged free Jan. 26th, 1920.

CASE 15.—Capt. P., 2nd Glosters. Type M.T. First attack, 1917; since 12. Four injections. Discharged free Feb. 18th, 1920.

CASE 16.—Lieut. B., R.F.A. Type B.T. First attack Baku, 1919, four injections. Discharged free.

CASE 17.—Lieut. F., R.A.F. Type B.T. First attack India, 1919; since 4. December, 1919, four injections. Reported hospital Feb. 7th, 1920. Quite free.

CASE 18.—Lieut. W., aged 24. Type M.T. Dec. 17th, 1919. M.T. parasites present. No history of malaria. Symptoms very pronounced—malaria, cachexia, anaemia, jaundice, vomiting. Urine bile-stained. Faeces normal in colour. Constipated. Dec. 17th temp. 104° F. First injection 0.3 g. N.K. Dec. 18th temp. normal. Patient feels better; jaundice commenced to disappear; and patient made uninterrupted progress. Discharged Jan. 28th, 1920, free and well. March 30th, 1920, reported at hospital; no recurrence. Feels quite well; weighs 13 stone.

CASE 19.—Major D., aged 35. First attack September, 1919. Type M.T. This was the most difficult case of all to deal with. Had nine intramuscular injections, one intravenous. Left hospital on May, 1920. Pathological laboratory report: No M.T. present.

CASE 20.—Capt. P. Type B.T. Jan. 3rd, 1920, first injection completed. Course of four. Feb. 21st, 1920, reports no recurrence.

Conclusion.

It will be noticed that in the 20 cases here reported 12 were Type B.T. and 8 Type M.T., none of which have reported a recurrence. To the above-mentioned I can add another 18 cases, of which I have

¹ Muir and Ritchie: Manual of Bacteriology, edition 1919, p. 506.

notes, thus making 38 cases in all. I may say that only three patients have reported "they think they have had a slight attack" since leaving hospital.

Personally I am very gratified with the results and regret I did not keep more records. In cases where it is doubtful if the malarial parasite exists in the blood I have tried a provocative dose, and in several cases the assisted result has been obtained. I would suggest that even two weeks after the blood gave a negative to M.T. or B.T. parasite, a mild provocative dose be given to ascertain whether a cure has been effected. If the disease is found to be latent a second course lasting another four weeks would be suggested.

In conclusion, I have to thank Major Essex Wynter, R.A.M.C. (T.), for permission to publish these notes; Captain W. L. Harrison, R.A.M.C. (T.), for his invaluable assistance in working out the pathological reports, especially as to the differential counts *re* large mononuclears; and Charge-Sister Brookes for her attention to the details regarding the preparation and after-care of the patients, the taking of temperatures, and valuable assistance given me in administering the injections.

A CASE OF ACUTE ENCEPHALITIS LETHARGICA FOLLOWED BY MYOCLONIC MOVEMENTS.

By A. CECIL ALPORT, M.D. EDIN., M.R.C.P. LOND.,
SPECIALIST IN MEDICINE TO THE ROYAL HERBERT HOSPITAL,
WOOLWICH.

THE following case has certain points in common with the three cases of the myoclonic form of acute epidemic encephalitis described by Dr. Arthur W. M. Ellis in THE LANCET of July 17th. The muscular spasms, however, in my case were a late sequela of the lethargic state, and instead of the shock-like contractions of the abdominal muscles with delirium and insomnia noted by Dr. Ellis, there was general muscular rigidity associated with drowsiness and coma; delirium and insomnia were minor features. The history of the case was obtained after the patient had recovered.

History of the Case.

Pte. J. went to Salonika in November, 1915. First attack of malaria in the summer of 1916; numerous relapses during 1916, 1917, and 1918. Since returning to England has had slight shivers and headache; last relapse in October, 1919.

Admitted to the Royal Herbert Hospital on Nov. 12th, 1919. Somewhat confused in mind; states he has had malaria. Lies with eyes shut, showing no interest in his surroundings, but answers when spoken to. Temperature 100° F.; pulse 84, good volume. Blood examination: No malaria parasites found.

Nov. 13th, 1919: Patient is dull and lethargic; has incontinence of urine and faeces. T. 99° 4'. P. 94. R. 36.

14th: Delirious and violent during the night; tried to get out of bed; very little sleep; quiet this morning; holds himself very stiff in bed, muscles of back being specially rigid; no vomiting; a few rales at base of right lung. It is impossible to palpate the spleen on account of the abdominal rigidity. T. 100°. P. 102. R. 36.

15th: No improvement. T. 99° 4'. P. 86. R. 36.
16th: Still very stuporose; incontinent. 12 noon: Gave rectal saline 8 oz., with quinine sulph. 20 gr. 5 P.M.: Nearly comatose; very rigid; conjunctival reflex extremely sluggish. Gave intravenous injection of quinine bihyd. 40 gr. in 8 oz. of normal saline at a temperature of 110° F.

17th: Patient has greatly improved; speaks intelligently. T. 101° 4'. P. 100. R. 36. Lumbar puncture attempted; no fluid withdrawn, patient too rigid for puncture without anaesthetic, and too ill to be anaesthetised to requisite depth. Blood culture negative after five days' incubation. Blood count: Total leucocytes, 9320 per c.mm. Differential count, neutrophil polymorphs, 83 per cent.; small lymphocytes, 7 per cent.; large lymphocytes, 5·5 per cent.; large hyalines, 2·5 per cent.; transitionals, 1·5 per cent.; basophils, 0·5 per cent.; eosinophils, 0 per cent. Urine: No albumin or sugar. Treatment: Rectal quinine 20 gr. night and morning, to be continued daily.

18th: More drowsy this morning. T. 100°. P. 106. R. 38. Case diagnosed as acute lethargic encephalitis by Dr. Newton Pitt, consulting neurologist to the hospital.

19th: Slightly improved. For the first time asked for and used the urinal instead of passing his water into the bed; no incontinence of faeces now. T. 101° 2'. P. 120. R. 40.

20th: Continued improvement; less lethargic, although he is still very rigid. T. 100° 2'. P. 114. R. 38.

21st: Patient is very much worse this morning; nearly comatose, can only just manage to put out his tongue, which is dry and covered with thick brown fur; muscles of back, abdomen, and limbs very rigid; has incontinence of urine and faeces. Rectal quinine saline not retained. T. 99° 2'. P. 112. R. 88. Although we had decided that the patient was not suffering from cerebral malaria, his condition was such that I resolved to repeat the intravenous injection of quinine. I was guided in this by the quite remarkable improve-

ment which had apparently resulted from the intravenous injection on the 16/11/19. Therefore, at 3 P.M., I gave him an intravenous injection of quinine, 40 gr. in 8 oz. of saline, as well as an intramuscular of 20 gr. I also ordered a rectal saline with quinine 20 gr. to be given at 11 P.M. At 10 P.M. the temperature had dropped to 97° F., P. 108, R. 40, and the patient appeared to be slightly better. 11 P.M.: Rectal quinine saline given but not retained.

22nd: Considerable improvement; much less rigidity of muscles; less drowsy; is more intelligent and understands what is said to him; on request made an attempt to whistle; no facial paralysis, ptosis, strabismus, or nystagmus, but states he sees double. T. 98° 4'. P. 96. R. 38. 11 A.M.: Intravenous quinine, 40 gr. in 8 oz. of saline. Intramuscular quinine, 20 gr. Tongue is still very dry and furred. 6 P.M.: Can move legs and arms freely; reflexes are normal, but still has rigidity of abdominal muscles and incontinence of urine and faeces. 11 P.M.: Retained rectal injection of quinine 20 gr.

23rd: Improvement maintained; can put out tongue without difficulty; organ dry and furred; is quite intelligent; got out of bed this morning, took some grapes from his locker and ate them; read his letters. Abdominal muscles remain rigid, but general rigidity has passed off; still has incontinence and diplopia. T. 98° 6'. P. 80. R. 36. Treatment: Intramuscular quinine, 20 gr., into each buttock. 6 P.M.: Rectal quinine, 20 gr.—retained. 11 P.M.: Rectal quinine, 20 gr.—not retained.

24th: Only slightly drowsy; speaks intelligently but slurs his words; sits up in bed when asked to; tongue furred but moist. T. 99°. P. 100. R. 36. 11 A.M.: Intravenous quinine, 30 gr. Intramuscular quinine, 20 gr. 6 P.M.: Rectal quinine, 20 gr.—retained. 11 P.M.: Rectal quinine, 20 gr.—not retained.

25th: Patient is making rapid strides towards convalescence. T. 99°. P. 86. R. 28. Says he is hungry and asks for food; sits up in bed smoking cigarettes; mentally clear; no sign of drowsiness; tongue quite moist and only furred on the posterior half. During the night, for the first time, he had no incontinence of urine. Throughout his illness he has been very constipated, and when he did pass a motion it was into the bed. On one or two occasions during his more lucid intervals he asked for the bedpan, but was unable to use it in time; has no incontinence of faeces now. Rectal quinine saline given t.d.s. and retained.

26th: Continued improvement. Second leucocyte count: Total whites, 20,400 per c.mm. Differential count: Neutrophil polymorphs, 68 per cent.; small lymphocytes, 16 per cent.; large lymphocytes, 15 per cent.; hyalines, 3 per cent. Quinine treatment stopped.

27th: Patient is better, but he has developed peculiar rhythmical movements of the right arm and leg; the finger movements have a strong resemblance to the athetosis of paralysis agitans; the arm and leg movements are choreiform in character.

Dec. 5th: During the past 10 days the patient's condition has greatly improved; speech is more distinct, and diplopia is no longer complained of. He has had slight irregular rises of temperature—99°. P. 98. R. 26. The arm and leg movements are worse, if anything, and he has sudden jerky spasms, due to contraction of the flexors of the limbs. He is able to feed himself, but very often an involuntary spasm of the muscles of the arm jerks the food he is carrying to his mouth over his shoulder or on to the floor. The mental state has improved, but he is depressed, very irritable at times, and difficult to nurse.

23rd: His general condition shows steady improvement; the temperature has been normal for a fortnight; there has been no return of the lethargic condition, but the rhythmical movements with sudden spasms are as bad as ever. There has been no diplopia or other sign of paresis of the ocular muscles since; his speech is more distinct and less slurring in character, but he is still depressed, irritable, and sleeps badly. He insulted the sister in charge of the ward this morning, and his behaviour at meals, on account of the unfortunate manner he has of jerking his food all over the table, has made him very unpopular with the other patients. Transferred to observation ward for mental cases. The report on blood taken for a Wassermann test is negative. Treatment: Pot. brom. 20 gr. t.d.s. and massage.

July 27th, 1920: Patient left this hospital six months ago, but I was fortunate enough to see him again to-day. He has almost recovered, and is able to go about London by himself. His mental condition is quite normal. His articulation is not absolutely clear yet, and he still has an occasional twitch of the right arm. He states that the twitching gets worse when he becomes over-tired. He sleeps, eats, and looks well.

I took the opportunity to have his eyes examined by the hospital ophthalmologist, who reports as follows: "Pupils react normally to light and accommodation; tension normal; convergence perfect; no abnormality of ocular muscles; says he has had diplopia, but not now. I am unable to find anything abnormal in the eyes."

Remarks.

Unfortunately I have no notes of the actual onset of disease except that the patient was taken ill at the Crystal Palace and that he had had malaria; there was no history of vomiting obtainable. The fever was of a mild type, but the pulse and respirations were rapid and continued so for months. No record was made of the condition of the pupils, although diplopia was noted. The speech was indistinct and slurring, and is still, after eight months, not quite clear. There was obstinate constipation and, after purgatives, incontinence of faeces. He had incontinence of urine for the first fortnight after admission; the urine showed no abnormality. The leucocyte counts are interesting. On Nov. 17th, 1919, there was a relative increase of neutrophil polymorphs, and the total count was more or less normal. Nine days later, when the patient was well on the road to recovery, the total number of leucocytes had risen to 20,400 per c.mm., the polymorphs had

fallen to normal, while the large lymphocytes had increased from 5.5 per cent. to 13 per cent. The latter rather points to malaria as a factor in the case. It was unfortunate that because of the rigidity of the muscles of the back and the fact that he took the anæsthetic so badly we were unable to obtain a specimen of his spinal fluid for examination; the Wassermann test on the blood was negative. The patient was delirious and violent on the third night after admission. His principal symptom was drowsiness; this deepened into coma on the fourth day, and after an interval of consciousness he again became comatose on the ninth day. Another marked feature was the rigidity, especially of the muscles of the back and of the abdominal wall. It is interesting to note that the abdomen remained rigid for some days after the general stiffness had disappeared.

As regards treatment, although parasites had not been found in his blood the treatment was carried out in accordance with the rule that all persons who have resided in a malarial district and suddenly become comatose should be treated with large doses of quinine by the intravenous and intramuscular or rectal routes.¹

The end in this case appears to have justified the means, and was characterised by a rapid return to consciousness after the initial coma on Nov. 16th, 1919, and again after the relapse on the 21st. I do not, of course, suggest that the recovery of this patient was due to the treatment he received, but the speedy manner in which he seemed to react to the intravenous injection of quinine gives food for thought.

The case may have been one of cerebral malaria—the history and second differential leucocyte count are in favour of this. On the other hand, it may have been some form of encephalitis—the rigidity of the muscles in the acute stage, the lethargy, the mental condition, the diplopia, the myoclonic movements in the later stages, and the first leucocyte count would appear to justify this diagnosis.

Clinically, apart from the result of the treatment, the case certainly did not conform to the type of cerebral malaria we saw in Macedonia.

Of the sequelæ the mental condition, the rhythmical movements, the sudden muscular spasms, the pill-rolling movements of the fingers and thumb, the absence of paralysis, the report on the condition of the eyes by the hospital ophthalmologist, and the slow but steady recovery of the patient should be noted.

THREE CASES OF ARTHROPLASTY.

BY C. D'OYLY GRANGE, O.B.E., M.B., F.R.C.S. ENG.,
ASSISTANT SURGEON, WARROGATE INFIRMARY.

THE following cases of arthroplasty following gunshot wounds of joints are described, as few similar cases seem to have been recorded, and they show that the limbs can be greatly improved by such operations.

1. *Gunshot wound of left buttock followed by dislocation of hip, with ankylosis.*—Pensioner J. T. was admitted to the Northumberland War Hospital in October, 1916, having been wounded more than a year previously. His chief wound was in the left buttock, the posterior lip of the acetabulum having been destroyed, and this had allowed of dislocation of the head of the femur on to the dorsum ilii. Here bony ankylosis had taken place with internal rotation of the thigh. The sciatic nerve had been partially injured. Drop-foot was present, and there were trophic sores on the toes. The right knee was ankylosed. When admitted there were several sequestra in the left ilium, and these were first removed. The wounds took a considerable time to heal, and the operation of arthroplasty had to be delayed owing to the fact that the trophic sores on the toes caused repeated attacks of inflammation in the skin and subcutaneous tissue of the leg and thigh. It would have been better if the foot had been amputated at this stage, as it had to be done later.

Operation.—On Oct. 6th, 1917, arthroplasty was performed, the neck of the femur being divided and a false joint made between the neck and head of the femur in the following manner. The patient lay slightly on his right side, with a sand-bag under the left buttock. A curved incision was made midway between the crest of the ilium and the great trochanter. The muscles were divided in the line of this incision until the neck and the head of the femur were laid bare. The head was firmly ankylosed on to the ilium. The tissues were freed from the neck, and it was then divided by a Gigli saw close to the head in an oblique direction,

the line sloping from above downwards and inwards. The lower part of the head was now cut away with a chisel and the upper part hallowed out to form a cup, into which the neck fitted after the edges had been rounded off. A flap of gluteus medius was then sutured over the raw end of the neck and a loose flap of fat from the buttock was placed in the cup in the head of the femur. The neck fitted quite well into this cup, and when the gluteus medius and minimus had been sutured there was no tendency for it to become displaced. The wound was completely sutured and a Liston splint with weight extension was applied for two weeks. Healing was slightly delayed by the presence of a hæmatoma, which would have been avoided by the use of a small drain; but in spite of this the patient very quickly began to move his limb and to sit up in bed, and within two months he could flex his hip to a right angle. The condition of his foot did not improve, and accordingly a Syme's amputation was done in March, 1918. This, however, allowed of the fitting of an artificial limb, with the result that the left leg was equal to the right in length, and he began to walk. When seen in January, 1919, he could flex the left hip to a right angle, and stated that with his artificial leg he could walk seven miles. He considered the left leg better than the right, owing to the ankylosis of the knee on that side.

This operation is a little more difficult when the head of the femur is ankylosed in the acetabulum because the neck is deeper. Murphy's method of sawing off the great trochanter might be easier, but I have not tried it.

2. *Gunshot wound of right shoulder followed by ankylosis.*—The patient, Corpl. M. M., was wounded by shell in March, 1916, and was admitted to the Northumberland War Hospital in April. Several pieces of metal had entered his right shoulder from above, causing a large flesh wound, fracturing the clavicle and the acromion, and passing down into the head of the humerus and into the arm. In May several loose pieces of bone and some pieces of metal were removed from the head of the humerus, and the cavity was filled with B.I.P.P., but the wound did not heal. In August the B.I.P.P. and some sequestra were removed, and a long tract was found passing four inches down the humerus. Stereoskiagrams revealed a piece of metal embedded in the bone, and this was removed through an incision posteriorly. The wound then healed. The result was ankylosis of the shoulder-joint in a slightly abducted position, with a good deal of destruction of the head and great tuberosity; the fractures of acromion and clavicle united, and there was a good deal of scar tissue above the shoulder where the skin wounds had closed. The condition of the patient was not good, he was very anæmic and thin, so nothing surgical was done for some time. He found the arm of very little use to him, as with scapular movement he could only abduct it 30°. This movement was probably limited owing to the injury to the outer end of the clavicle, and consequent limitation of movement of the acromio-clavicular joint. Flexion of the arm was almost nil and there was no rotation.

Operation.—On April 14th, 1917, arthroplasty was performed. An incision was made along the lower border of the clavicle and down the front of the arm for three inches, another was made just below the acromion process to meet the first incision, and a third was made along the lower border of the pectoralis major; this last, with the clavicular part of the first, allowed the flaps of fascia to be taken off the pectoralis major. The pectoralis major was divided where it crosses the axilla, and the anterior half of the deltoid was also cut through half an inch below the acromion process and turned down. This exposed the short head of the biceps and coracobrachialis arising from the coracoid process; these were divided, as was also the pectoralis minor. The vessels and nerves were pushed downwards and inwards, the subscapularis was exposed and divided, and the head of the humerus thoroughly exposed. There had been a good deal of destruction of the head and a considerable amount of outgrowth of bone, with the result that the head of the humerus was very irregular in outline, and considerable difficulty was experienced in freeing the capsule and muscles on the posterior surface. When this was done a large joiner's chisel was used and the humerus was separated from the body of the scapula as near the joint line as possible, but a part of the axillary border of the scapula came away with the humerus, and it had to be excised. The head of the humerus was rounded off as much as possible and the glenoid smoothed down, and then a large flap of superficial fascia was turned in from the surface of the pectoralis major. The flap was hinged externally by two pedicles, which allowed of the muscles being sutured between them. The subscapularis muscle was then sutured, followed by the coracobrachialis, short head of the biceps and pectoralis minor, and, lastly, the deltoid and pectoralis major. The long tendon of the biceps must have been destroyed during the earlier months of suppuration, for it was not present over the upper part of the humerus. The wound was closed and the arm put up with the shoulder abducted 45°. There was considerable oozing during the whole operation and for several days after; the patient always bled freely. A small part of the pectoral flap, being very thin, sloughed, and a sinus remained over the head of the humerus. After repeated skiagrams and examinations with a probe, with negative results, the sinus was opened up and a sequestrum was removed. It was evidently one of the chips from the head of the humerus which had been overlooked, and after its removal the wound healed. The result of the operation, considering the amount of damage done by the wound, was good. Active abduction to 45° and flexion to 45° could easily be obtained quite painlessly, together with 60° of rotation. Passive flexion and abduction could be obtained to 90°.

3. *Gunshot wound of right elbow followed by ankylosis.*—Pte. F. D. was admitted in April, 1918, having received several wounds on the outer side of the arm and forearm about ten days previously, one of which opened up the elbow-joint. The wounds were dressed with B.I.P.P. and healed in eight weeks, but complete ankylosis of the elbow at an angle of 90° resulted, without, however, any loss of bone. The arm was treated with radiant heat and massage for two months, and then arthroplasty was done on Sept. 3rd.

Operation.—An incision 4 inches long was made on the outer and one on the inner side of the joint, and these were joined by a transverse incision across the arm above the olecranon. The ulnar nerve was dissected out and retracted inwards to avoid any

¹ Alport: Malaria and its Treatment, p. 56.

injury, the triceps muscle was divided transversely an inch above the olecranon, and the humerus exposed. The triceps was dissected down, both internal and external lateral ligaments were divided, and the olecranon and head of the radius exposed. A half-inch chisel was driven in, first on one side and then on the other, between the olecranon and radius on the one hand and the humerus on the other, keeping as close to the line of ankylosis as possible. The radius was easily separated by this means, but the ulnar was fixed by the ankylosis of the coronoid process and humerus; this was readily broken through by flexing the forearm. The surfaces of the bones were now very like the surfaces of the normal bones in shape, but very rough. They were smoothed down as much as possible, and made to fit and move easily the one on the other. The ankylosis between radius and ulnar was only fibrous and was cut through. A flap of fat from the posterior surface of the triceps was then turned into the joint and sutured to the anterior capsule, a piece of Cargile membrane being placed on each side of the flap. The triceps was sutured together and the skin closed, the arm being put up at right angles. Gentle movement was started in ten days' time, but it was painful. Massage was commenced at the end of three weeks.

The patient was discharged in January, 1919, his movements being flexion 30° beyond a right angle and extension 45° from a right angle. Pronation and supination were disappointing, as it only amounted to about 30° . Flexion and extension were very powerful movements, as he had full use of his biceps and triceps, and there was no lateral movement at the joint owing to the preservation of the original contour of the bones. The amount of movement obtained might have been improved by the excision of more bone, but I think the joint would have been less secure and the power of movement lessened.

Conclusions.

The operations have little risk, and the benefit in each case was considerable. The joints were very strong and there was no tendency to dislocation or to abnormal movement, as the chief ligaments remained.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF PURPURA FACTITIA.

By KATHLEEN M. McKEOWN, M.B., B.S. LOND.,

HOUSE PHYSICIAN, VICTORIA HOSPITAL FOR CHILDREN, CHELSEA.

THE following case is a typical instance of hysterical deception, confirmed by the confession of the patient.

A girl of 13 was admitted to hospital on April 22nd, 1920, for "purpura," when she gave the following history. On April 17th she had not felt well, had vomited once, and had complained of pains in both arms not limited to the joints. She stated that large purple patches, not painful on pressure, had appeared all over her arms and legs on the same evening, and that her elder sister had had similar patches all over her body some years before. No history of rheumatism was obtained. The patient belonged to people in extremely poor circumstances and was rather hysterical in type. Since March 3rd she had attended the hospital as an out-patient as she had fallen down a flight of stairs, and she was about to be discharged on April 17th.

Condition on admission.—Temperature, pulse, and respiration normal. On examination there were seven large "purpuric" patches, varying in size but not in shape, on the flexor surfaces of both arms and forearms, with three similar patches on legs. The highest patch on the right side was on a level with the tip of the acromion process. The patches on the legs were on the inner and outer surfaces midway between the knee and ankle. The patches consisted of numerous minute hemorrhagic spots and petechiae set closely together and presenting a definite grouping. There was an outer band representing the outline of an oval and two straight lines somewhat broken running along the long axis. All the patches with the exception of two were oval, measured 2 in. by 1 in., and were very sharply defined. The two exceptions were on the arms and were linear, starting on the extensor surface and coming round to the flexor surface. The rest of the physical examination was negative.

At a first glance purpura was suggested, but a suspicion of self-infliction was aroused by the similarity in shape and size of the majority of the patches, the curious shape, the position and distribution, and lastly, the absence of any purpuric manifestation elsewhere.

During the first examination it was easily shown that all the marks occurred on places accessible to the patient's mouth, and later we were able to prove experimentally that similar patches could be produced by taking hold of a piece of skin with the teeth and then applying strong suction with the lips. The existing patches were ringed with silver nitrate, and the patient was given ample opportunities for producing fresh ones, but none appeared. After three days the patches became brown in colour and faded in a week.

A CASE OF BLACKWATER FEVER; RECOVERY.

By EDWARD F. GREENE, M.R.C.S., L.R.C.P. LOND.,

HONORARY CAPTAIN, R.A.M.C.

THE following details of treatment of a case of blackwater fever, which proved to be very satisfactory, appear interesting enough to warrant publication. The patient came on board the s.s. *Zaria*, West African mail boat, at Duala on July 14th, 1920, and was perfectly well up to 11 P.M. on July 22nd. On July 23rd at 1 A.M. he was taken ill, the symptoms beginning with epigastric pain, sickness, and the passing of coffee-coloured urine. The patient stated that two men employed at the same factory as himself had recently died of blackwater fever.

Course of the disease and treatment:—

July 23rd: 11 A.M., temp. 105.5° F. (phenacetin, gr. x.), water dark brown, one quarter albumin. Half a pint of hot water with one teaspoonful of salt given every half hour, 10 gr. of phenacetin every two hours. A hypodermic injection of hyd. perchlor., 1 in 1000 (10 minims dose), given at 9 A.M.; temp. 9 P.M., 102.5° .

July 24th: Water slightly lighter, but redder, albumin one quarter; 10 A.M., temp. 99.5° .

July 25th: 9 A.M., temp. 102.5° . Inject. hyd. perchlor., 1 in 1000 (M x.), temp., 9 P.M., 99.8° .

July 26th: Temp. 102° . Repeat injection of hyd. perchlor. and saline solution being given continuously throughout. 9 P.M., temp. 102° ; urine bright red.

July 27th: Temp. 98.4° . Saline solution still given. Albumin, trace only.

From this date the temperature continued normal, the urine became normal, and the patient made a rapid recovery. By August 3rd he was able to resume normal conditions.

I attribute the successful recovery to the continuous use of the saline solution and the injection of the 1 in 1000 perchloride of mercury solution.

A CASE OF PYORRHOEA ALVEOLARIS.

CAVERNOUS SINUS THROMBOSIS; HEMIPLEGIA.

By R. ECCLES SMITH, F.R.C.S. EDIN.

IN THE LANCET of August 2nd, 1919, I recorded under "Intracranial Lesions" a case of the above condition which is of rare occurrence. Yet within two years I have to note a further case, demonstrating the urgent need and great value of attention to the teeth both in the adult and the child.

The patient, a girl of 24 years, had a perfect cesspool in the upper jaw. She was treated for five days for an increasing swelling of the left side of the face and oedema of the left eyelid. Paralysis of the right side ensued, and she was sent to me moribund. Pronounced pyorrhoea, ulcerative gingivitis, ulceration of the cheek adjacent, with a spreading cellulitis of the face, led the way to the cavernous sinus via the pterygoid plexus of veins. Extreme proptosis of both eyes and chemosis, especially on the left side. Involvement of the left crus cerebri by its close relation to the cavernous sinus, with corresponding right-sided hemiplegia. (Edema over the left mastoid (via the petrosal sinus) completed the ghastly picture of cavernous sinus thrombosis. Death ensued in 12 hours from profound septicæmic coma, six days after the onset of symptoms.

Apart from all the minor miseries and ill-health caused by septic infection of the teeth, I think these two fatal cases should promote further interest in the question of even compulsory dental inspection and treatment.

Barry, Glam.

DEATH OF DR. A. W. D. HUNT.—Albert William Dunning Hunt died at his residence, Heylands, Chagford, Devon, on August 27th, in his forty-fifth year, after a long illness. Dr. Hunt was highly esteemed in and round Chagford; he was devoted to the people of Dartmoor, where his father and grandfather had been in practice before him. He qualified M.R.C.S., L.R.C.P. from the Middlesex Hospital Medical School in 1899, and held the appointments of house physician at the Hospital for Consumption, Brompton, and house physician and house surgeon at the Oxford County Hospital before settling in practice. He held several public appointments and was honorary surgeon to the Moretonhampstead Cottage Hospital. Dr. Hunt will be greatly missed in Chagford, and much sympathy is felt there for his widow and three young children.

Reviews and Notices of Books.

THE PATHOLOGY OF WAR GAS POISONING.

Collected Studies. By M. C. WINTERNITZ, Major, M.C., U.S.A. London: Humphrey Milford; Oxford University Press. Newhaven: Yale University Press. 1920. Pp. xxi. + 165. 41 plates. £4 4s.

IN his collected studies, issued by the Oxford and Yale University Presses, Major Winternitz presents a handsome monograph on the pathology of war gas poisoning, based on the researches of his own department of the Chemical Warfare Service, U.S.A. The work deals almost exclusively with pathological anatomy and morbid histology of the organs of experimental animals examined at various intervals after exposure to warfare gases. The changes observed in the respiratory system during the acute period of poisoning are described with great care for each of the toxic agents dealt with, and attention is again drawn to the two main types of lesion produced: on the one hand epithelial destruction, especially in the upper air passages; and, on the other, damage of the lung capillaries with resulting pulmonary oedema. According to the degree in which one or other element predominates the gaseous poisons may be arranged in a series at one end of which stands phosgene, an almost purely pulmonary irritant, while at the other end may be placed mustard gas, which exerts its effects almost exclusively on the air passages, producing membranous tracheitis and bronchitis. Chloropicrin, chlorine, and the phenylarsines come intermediately, producing both effects; in the order named they cause successively less pulmonary oedema and more epithelial damage, the results being fairly characteristic for each individual agent. In relation to the oedema of the lungs it is remarkable that Winternitz has failed to observe the specific damage to pulmonary capillaries, with thrombosis, which British and other observers have repeatedly described; the omission is possibly due to the placing of too much reliance on special fibrin staining for the recognition of thrombi.

Following the description of the acute phenomena due to the poisons themselves there is given an account of the inflammatory changes which result from subsequent infection. In dogs, which were most often used, infection occurred with great regularity and often produced fatal results in animals which would have recovered from the effects of the gas alone. In the British experiments on goats infections played an inconspicuous rôle, and it is probable that in this respect human victims occupy an intermediate place as regards susceptibility. The section of the book which at the present time possesses the most directly practical value deals with late and permanent effects of gassing, studied at periods up to six months after exposure. The most important lesions found during this period are emphysema, bronchiectasis, collapse of lung, and obliterative bronchitis, all of which may be complicated by chronic septic foci from which acute lesions may arise from time to time. In the final chapters some preliminary observations are given on experimental lavage of the lung through the trachea with a view to washing out irritant materials which have lodged there.

The book is profusely illustrated by excellent coloured drawings. While it is improbable that this work will now appeal to a wide public, it forms a record of experimental observations of high scientific value, and it will prove an interesting and suggestive book of reference to those who may still have to deal with the late effects of gas poisoning in soldiers.

GONOCOCCAL INFECTION IN THE MALE.

By NORMAN LUMB, O.B.E., M.B., B.S. London: John Bale, Sons, and Danielsson. 1920. Pp. 328. 25s.

THIS work gives a plain straightforward account of the treatment of gonorrhoea in the male. Only those methods of treatment are described which have definitely proved successful in the hands of the author;

the book is eminently a practical one, and little space is devoted to questions of theory. The description of the various methods of treatment is clear and assisted by excellent illustrations. Mr. Lumb believes that skill in the use of the urethroscope is essential to the successful treatment of gonorrhoea, and for this reason devotes considerable space to the subject of urethroscopy. This portion of the work is enriched with coloured plates illustrating the various appearances, both normal and abnormal, that are to be met with during the process of urethroscopy. A complete chapter is allocated to the subject of keratoderma blennorrhagica, in our opinion a somewhat over-liberal allowance. On the other hand, that all-important subject, the standard of cure, is squeezed into a chapter devoted to a consideration of impotence and sterility. However, in spite of certain features inviting criticism Mr. Lumb's book affords a good and practical description of the treatment of gonorrhoea. It will be useful to those who already possess a certain knowledge of the subject, but who are lacking in those refinements of technique that make the difference between success and failure.

GRUNDRISS DER PHYSIOLOGIE FÜR STUDIERENDE UND AERZTE.

Von Professor C. OPPENHEIMER (München) und Professor OTTO WEISS (Königsberg i.Pr.). Erster Teil. Biochemie, von C. OPPENHEIMER. Dritte Auflage. Leipzig: Georg Thieme. 1920. Pp. 522.

THIS volume on biochemistry is the first part of the Grundriss, to be followed by the second part on Biophysik, from the pen of Professor Weiss. The second edition, already set up in 1915, was not published until 1918, and the author, while thoroughly revising the whole work, has, in the new edition, striven to give a clear and comprehensive view of the bases of the modern physiology of the cell, and has in particular rewritten the chapters on colloids, cellular metabolism, permeability, and allied phenomena, and added some matter on the pathology of metabolism—e.g., gout and diabetes—to give the effort a more "practical outlook." The biophysical part—which has not yet reached us—will deal with general nerve physiology, the physiology of movement, heart, blood-vessels, and circulation, movement of lymph, digestion, central nervous system, and sense organs, temperature, and heat formation.

In this part 268 pages—the systematic part—are given to the chemical constituents of the animal body, wherein is embodied a sufficient account of the acyclic and carbocyclic compounds, animal proteins, ferments, antigens, and antibodies. The substances of the fatty series are first dealt with, waxes, fats, lipoids, and carbohydrates are followed by benzene derivatives, aromatic compounds, purins, then the general and special chemistry of proteins. The chapter on the ferments—i.e., enzymes—seems to us both terse and comprehensive. To hydrolytic ferments as a group the term hydrolases is applied, including esterases, carbohydrases, glucosidases, amidases, and proteases. The remainder of the text is called the analytical-physiological part and deals with the chemical functions of the tissues and the organism, including the composition of living matter, foods, metabolism, intake and transport of foodstuffs including the chemical aspects of digestion, digestive secretions, absorption blood, gaseous exchanges in lungs and tissues—secretion and excretion, regulation of functions including liver, blood-forming organs, internal secretions and hormones, and lastly, supporting tissues, nerves, and muscles.

For accessory food factors or vitamins, the term "nutramines," invented by Abderhalden, is used, and so is another of his terms—viz., "increate," for internal secretion. In dealing with the secretion obtained from the pyloric mucous membrane, Bickel's name is mentioned, but not that of Edkins. Some interesting speculations are given (p. 386) as to the significance of so-called proteinogenic amines, including histamin, adrenalin, and tyramin, and their relation to endocrine glands. As the potential substances in internal secretions are chemical in nature, their general and special physiology is relatively fully dealt with.

The book is a well-balanced exposition of what the Germans regard as bio-chemistry, the physiological significance of the chemical data being made to stand out significantly.

MILITARY SANITATION.

A Handbook for Soldiers. Third edition. By Colonel ROBERT J. BLACKHAM, C.B., C.M.G., C.I.E., D.S.O., &c. London: John Bale, Sons, and Danielsson, Ltd. 1920. With index. Pp. 140. 10s. 6d.

A BOOK on military sanitation which has reached a third edition is clearly satisfying a want. It is written for officers and non-commissioned officers of the Service generally, and can be carried in the tunic pocket. It is well adapted to teach those without a previous medical training the principles and practice of hygiene; their resulting knowledge will be very exact. The quoted opinions of great soldiers are impressive and arresting, but might be more numerous. Amongst books on military hygiene perhaps the most pleasing particular feature of this little work is that detailed schemes are put forward for regimental or orderly officers inspecting kitchens (p. 72) and sanitary areas (p. 90), telling them most helpfully, line by line, where the most probable neglects in sanitary precaution will manifest themselves, and how, therefore, they may be quickly discovered. In the next edition it might be well to develop this idea further and to suggest a routine for establishing the health administration of a battalion when first formed, dumped, for example, as battalions were in 1914, on Salisbury Plain, with possibly no one of experience to guide them. To this might be added a suggested routine for carrying on the sanitation of the battalion when it has been set going and only wants to be kept up to its level. It is noticeable that "ventilation" does not occur in the index, nor is it suggested in relation to the "protective measures" against influenza or pneumonia in the very interesting chart of infectious diseases with which the book ends. There is on p. 39 an encouraging account of how the army fitted a square peg in a square hole, and Colonel Blackham's directions for waterproofing uniform with lanoline will be found very helpful if we ever have war in Europe again. He gives a good account of boots, emphasises the valuelessness and positive dangers of flannelette, and, directing particular attention to the soldier's socks, insists he should have, or, as they say in the army, "be issued with," four pairs, one more than now allowed. The book is handy, readable, and well printed.

A MANUAL OF ELEMENTARY ZOOLOGY.

Third edition. By L. A. BORRADAILE, M.A., Lecturer in Zoology in the University of Cambridge. London: Henry Frowde and Hodder and Stoughton. 1920. Pp. xvii. + 616.

To have reached a third edition in these days of competition among text-books of zoology argues the possession of merits of a definite order. That the author is accurate in his statement of facts is, of course, satisfactory, but does not call for so much appreciative comment as in former years when types were less stereotyped. It would be difficult to make nowadays a real "howler" in the account of the anatomy of crayfish or frog, though in former years the late Professor Milnes Marshall remarked upon the "quite curious difficulty" of weathering rocks and quicksands when dealing with the most ordinary material of zoology.

Mr. Borradaile, in producing even so restricted a work as this one, has had to grapple with whole libraries of zoology, and his problem in writing, as ours in reviewing, an elementary manual of zoology, must be mainly concerned with judgment and balance in selection. He is compelled to devote much space to some animals and to some views and to neglect others. For instance, he has said nothing at all about sponges. There would seem to be a fate in this. Two text-books, at any rate, are known to us of a more or less general applicability in which the same group is ignored. The writer may, however, be justified in neglecting a group the sterility of which has been emphasised by zoologists; sponges appear to "lead to nowhere in particular."

Since this text-book is addressed mainly to medical students Mr. Borradaile is wise in laying stress upon those animals and groups of animals which have a bearing upon medicine and surgery. Parasites are dealt with fully and in connexion with disease. There are also chapters, or at least sections, upon matters of wide interest, such as Mendelism, Natural Selection, Fertilisation, and so forth; in fact, we cannot accuse the author of any serious omissions in these departments. Indeed, if more had been stuffed in something would have had to give place, and it is not easy to see what could best have been spared from what is a manual and not a treatise.

DIABETIC DIETING AND COOKERY.

By P. J. CAMMIDGE, M.D. Lond. London: University of London Press, Ltd. 1920. Pp. 222. 10s. 6d.

PERHAPS the greatest advance that has been made of recent years in the treatment of disease is to be found in the case of diabetes. In this book of Dr. Cammidge's both the busy practitioner and the patient suffering from diabetes will find set out in a simple manner the details of the newer methods. A patient of ordinary education with the information here provided will be able to coöperate intelligently with the physician in carrying out those precise changes in diet with which present-day treatment so largely concerns itself. Should complete abstinence from food be prescribed for one, two, or three days he will understand the *raison d'être* of the prescription and be all the more eager to carry it out. Quantitative regulation of diet, at first sight so difficult to effect in ordinary life, becomes comparatively easy to a patient trained for a week or two in weighing out quantities and learning by experience the weight of average servings of the common articles of food in the manner here suggested. Two very useful chapters deal with diabetic cookery and cookery recipes. In the latter upwards of 200 recipes serve to afford variety to what in the past, in too many instances, has been a daily round of monotonous menus. We question the wisdom of including the chapter dealing with diabetic coma in a book intended to be placed in the hands of sufferers from diabetes, nor are we convinced that "every patient should know how to test his own urine for sugar and adjust his diet according to the results obtained." Apart from these objections we have nothing but praise for a volume which meets a long-felt need.

MEDICO-TROPICAL PRACTICE.

A Handbook for Medical Practitioners and Students. Second edition. By GILBERT E. BROOKE, M.A., D.P.H., Chief Health Officer, Straits Settlements Government Medical Service, &c. Revised throughout and rewritten. London: Charles Griffin and Co., Ltd. 1920. With 61 illustrations. Pp. 522. 18s.

THE author has changed the title of his book from Tropical Medicine, Hygiene, and Parasitology to that of Medico-Tropical Practice, a change which has only brevity in its favour. The first edition appeared in 1908 and had a deserved popularity. The present volume contains 37 chapters, with an appendix and an index. There are some useful illustrations, and as most of the text is up to date the information should prove of value to students and tropical practitioners. We note the adoption of *Loeschia* as the generic name of the amœbæ of man, but miss any reference to the recent work of Dobell and others on *Endolimax nana*, *Iodamoeba butschlii*, and *Dientamoeba fragilis*. This is unfortunate. Some of the old names are still retained for the flukes, such as *Opisthorchis*, which should now read *Clonorchis*, and *Cotyllogonimus* instead of *Heterophyes*.

No mention is made of Noguchi's work on spiro-nemata in yellow fever, nor is the new antimony treatment for bilharziasis dealt with. Omissions such as these are unfortunate as regards the teaching of students and impair the value of the work as an up-to-date handbook. The incorporation in a future edition of such new work will make the book of real value to students and junior practitioners. Parts of it now are excellent.

JOURNALS.

Journal of Hygiene. Vol. XIX., No. 1. July, 1920. Edited by G. H. F. NUTTALL, F.R.S.—This issue contains interesting articles on bacteriological and hygienic subjects. The attention of pathologists is drawn by the editor to the Second International Congress of Comparative Pathology, to be held in Rome in April, 1921.¹ Tetanus: Analysis of 1458 Cases which Occurred in Home Military Hospitals during the Years 1914-1918, by Sir David Bruce, K.C.B., F.R.S. This interesting and useful summary was dealt with in a leading article last week. Reference may here be made to one or two special points. Sir David Bruce shows, we think, quite clearly that the prophylactic use of serum was effective in cutting down both the incidence and the mortality of the disease, though he believes that thorough surgical treatment of wounds was of very great importance. The therapeutic use of serum was, however, disappointing, as was to be expected from the knowledge already gained before the outbreak of war. Professor Sherrington's work, which established the intrathecal route as the best for administration of the serum, is referred to. Anaphylactic shock occurred in 49 cases of tetanus treated with serum, with 12 deaths. Of these cases of shock, 17 were caused by intrathecal injections, 14 by intravenous, 9 by intramuscular, and 2 by subcutaneous. Anaphylactic shock was thus not a rare phenomenon.—A Study of the Serological Reactions of Meningococci and an Account of the Method of Preparation of Antimeningococcus Serum, by A. Stanley Griffith, M.D. The first part of this long article is devoted to an account of work on the separation of types of meningococci by means of the agglutination reaction. The author concludes that "Gordon's classification holds good if care is taken in the selection of strains for the production of type sera," but that "all the strains included in each type are not identical in their serological characters," and that "there is inter-relationship between the types." In the second part of the paper Dr. Griffith discusses the methods of preparing anti-meningococcal serum.—Carriage of Coliform Bacilli by the Oriental Hornet (*Vespa orientalis*, Fabr.), by P. A. Buxton, M.A., M.R.C.S. The author examined, by dissection and by plating on McConkey's medium, the gut contents of the large red oriental hornet which is common in Mesopotamia. The hornet is a foul feeder, and Dr. Buxton shows that of 64 examined 23 were carrying well-known types of intestinal bacteria.—On Defence Rupture and the Antagonistic Action of Salts, by C. Shearer, F.R.S.—Report of Experiments on the Cold Storage of Herrings Carried out at North Shields (June and July, 1919), by Ione H. Green. The author draws the following conclusions from the work described in this paper—that brine-freezing is more satisfactory than dry-freezing, and that ungutted frozen fish keep better than gutted ones. The need for the most elementary measures of cleanliness in the handling of fish is pointed out. At the present time apparently waste is common owing to the lack of proper organisation in the fishing industry.—An Inquiry concerning the State of Cleanliness of Empty Milk-churns, by R. H. Cumming and A. T. R. Mattick. It is shown in this investigation that the present inadequate methods of washing and cleansing churns is one cause of the loss of milk through souring in transit.—Suggestions for a New Criterion of a Positive Wassermann Reaction Based on an Analysis of 2334 Quantitative Tests, by C. H. Browning and E. L. Kennaway. The new criterion is "based upon a comparison of the amounts of complement giving complete lysis with any given serum, and with the negative control, respectively." The article will be read and studied by those who are occupied in carrying out the Wassermann reaction.—The Milk-supply of the City of Edinburgh, by A. Cunningham and B. A. Thorpe. The authors examined 40 samples of milk from the supply of the city of Edinburgh, and found that the bacterial content was of about the same order as that reported from other large cities. They recommend the reductase test for obtaining a rough idea of the numbers of bacteria present in milk.—The Wilson-Weil-Felix Reaction in Typhus Fever, by W. James Wilson, M.D., D.Sc., D.P.H.—This article gives a valuable historical account of the reaction as diagnostic in typhus fever. The author suggests that the explanation of the occurrence of agglutinins to the proteus bacillus X19 is that in typhus fever a bacterium, which is a normal inhabitant of the human intestine, gives rise to agglutinins for itself and group agglutinins for numerous other organisms, especially X19 and X2 proteus bacilli.

Quarterly Journal of Microscopical Science. Edited by Sir E. RAY LANKESTER, K.C.B., F.R.S., &c., with the co-operation of Professors HICKSON, F.R.S., GILBERT BOURNE, F.R.S., J. GRAHAM KERR, F.R.S., and E. W. MACBRIDE, F.R.S. Vol. LXIV., Parts 2 and 4.—*Journal of the Royal Microscopical Society.* Edited by C. SINGER, M.D., with the assistance of Professor J. ARTHUR THOMSON, LL.D., Messrs. DISNEY, I. G. RAWLINS, DR. RENDLE, F.R.S., and Dr. R. ST. JOHN BROOKS, M.A., M.D. 1919, Part 4; 1920, Part 1.—

The two parts of the *Quarterly Journal of Microscopical Science* noticed here contain between them seven memoirs, all of which are of importance.—In a memoir on "Determination of Age in Honey Bees," Mrs. Goodrich states that these insects die not only from various bee diseases or from violence, but perish worn out by work and old age. It would appear that in the height of the honey-flow worker bees literally work themselves to death about six weeks after hatching. Mrs. Goodrich points out that such bees, not suffering from any bee disease, can not only be recognised by their worn appearance and frayed wings, but an examination of the brain cells establishes their senile condition. Figures of these cells in freshly hatched insects and in those of greater age show obvious degenerative changes in the latter. From the economic point of view it is clearly important to be able to distinguish between those insects which are suffering from a possible unknown bee disease and those which are merely senescent and dying.—A second paper of great interest, by Professor Hickson, concerns the re-discovery of *Protohydra leuckartii* in this country. Originally—and as long ago as 1868—Professor Greeff found this simple organism—which is practically a hydra without tentacles—at Ostend, near which town it was again found in 1892. It has now cropped up in tidal marshes near Southampton, and in a postscript Professor Hickson announces that further specimens have been found near Plymouth. He details such facts as he has noted from the examination of abundant material regularly supplied to him at various periods of the year; hitherto he has been unable to find any trace of any medusa stage.—As to the other communications in the journal Professor Gemmill continues his well-known studies among the Echinodermata in a memoir upon the development of *Crossaster papposus*, while Mr. Bronte Gatenby continues his series of articles on the Cytoplasmic Inclusions of the Germ Cells.—The *Journal of the Royal Microscopical Society* contains, as usual, a few memoirs read to the Society, and a mass of abstracts of current research on both animals and plants. The latter, as has been customary in recent years, bulks most largely, and is of the greatest use to workers in all departments of biology. It forms a useful supplement to the lists of titles of papers published annually in the Zoological Record, and its value is enhanced by a few woodcuts. It includes a good summary, with three illustrations, of the recent well-known investigations on the "spiroptera cancer" in rats, with special reference to the part played by the cockroach.

British Journal of Experimental Pathology. Vol. I., No. 3. June, 1920. Editors: C. H. BROWNING, P. FIDES, W. E. GYE, E. L. KENNAWAY, E. H. KETTLE, J. MCINTOSH, J. A. MURRAY, W. J. TULLOCH, C. M. WILSON. London: H. K. Lewis and Co., Ltd. Price 7s. 6d., annual subscription £2.—The third number of this journal maintains the high standard of previous numbers. A leaflet is enclosed containing a series of summaries of all the papers published up to the present in the journal. These summaries are concise, and are printed in small type, occupying just enough space to be convenient for a card-index system. This novel and useful innovation is apparently to be continued in subsequent issues. The Antigenic Properties of *B. psittacosis*, by H. M. Perry. The organism was isolated from a grey touracou native to South Africa. The investigation was undertaken to establish the identity of the organism. It was found that the antigenic properties of the bacillus are identical with those of the "mutton" type of *B. aertrycke*.—A Method for the Estimation of Urea by Soy-Bean, by E. L. Kennaway. The method detailed is simple, gives accurate results, and should therefore be of great practical importance in the clinical laboratory. Amounts of 1 mg. of urea can be estimated by the method with an accuracy of 97 per cent.—The Value of the Vital-red Method as a Clinical Means for the Estimation of the Volume of Blood, by D. T. Harris. The method of estimating the volume of blood by means of innocuous dyes depends upon the introduction into the vascular system of a known weight of the dye, and then, after allowing time for the dye to become uniformly distributed and before passage of the dye from the vessels begins, to take a sample of blood and estimate the concentration of the dye therein. Vital-red is, from the standpoint of safety and simplicity, the most useful substance for the determination of the blood volume of man. Its reliability has been tested by Dr. Harris, who finds out that, owing to the rapidity with which vital-red leaves the vessels, the method gives results which are too high. The optimum interval for taking a blood sample is two to two and a half minutes. The correction-factor for cats and dogs for a four-minute interval is 0.78, for a one-minute sample 0.9. For man the correction-factor probably lies between 0.8 and 0.9.—The Etiology of Influenza, by P. Fides and J. McIntosh. This article completes the review of the subject begun in the previous number. The authors weigh the evidence for and against the view that influenza is caused by a filterable virus, and conclude that the balance is against this view. Finally, the conclusion reached is favourable to the view that *B. influenza* is the specific microbic agent in influenza.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 11, 1920.

The Physician in the War.

UNDOUBTEDLY the surgeon had the time of his life during the years 1914 to 1919. He then obtained more operative practice in a few short months than would otherwise have fallen to his lot in a lifetime. He enjoyed skilled coöperation, with abundant opportunity of mutual help and counsel. In view of the circumstances no leave had to be wrested from relatives for performing biopsies or autopsies. The services of bacteriologist, registrar, and statistician were at his elbow. Surgeons from all parts of the country and from many civilised lands got to know each other as friends and professional colleagues, with lasting advantage to the fraternity of surgery. No wonder surgery made great advances. The time of the physician came later, and never so completely. The war needed him just as much, but at the outset no one in authority was clear-sighted enough to see this, although it is now obvious that the early recognition of epidemic disease was a matter on which the lives of thousands and tens of thousands might hang. The official stage appeared complete with the trilogy of surgeon, sanitarian, and bacteriologist, and although the diagnosis of all known and some unknown infectious diseases was in reality a task for the highest medical ability, it was not until the campaign was half over that the consulting physician began to take his due share in affairs on the field of battle and behind the lines. What this share was is attractively portrayed in the first Lumleian lecture, which we print on another page.

War conditions made the physician's work essentially different from that of civil practice. In the first place the opportunities of group study were almost boundless. Not only infectious diseases but maladies of all kinds were notified, and during the latter part of the campaign facilities were such that the physician could take his choice of a syndrome which interested him and work it out in various areas of the vast field of hostilities. In spite of the great relative improvement in hygienic conditions since the Crimean war, of which sanitarians never weary of telling us, and the remarkably small proportion of disease during the whole campaign, still, as Sir JOHN ROSE BRADFORD reminds us, the actual numbers of sick were far larger than those of wounded. Interest was not limited to the diseases generally recognised in association with campaigning. Typhoid, cerebro-spinal fever, trench fever, dysentery, and the like, had their special attraction to clinician and epidemiologist, but an impetus was also given to the study of such everyday disorders as acute rheumatism and lobar pneumonia. Sir J. ROSE BRADFORD remarks on the rarity of acute rheumatism in the field. With an unprecedented population of young males and a very large population of young females, exposed, as never before, to the rigours of wet and cold, this immunity would have been astounding had not Sir ARTHUR NEWSHOLME, when medical officer at Brighton, prepared us to associate acute rheumatism with dryness and warm spells of weather. The war-time physician has established beyond a doubt

this observation of the peace-time sanitarian. During his whole service in France Sir J. ROSE BRADFORD saw no death from acute rheumatism nor any case of rheumatic hyperpyrexia. Acute infective endocarditis, when it occurred, developed, as a rule, on healthy valves, and only rarely as an incident of gunshot sepsis. So much for rheumatism. The war also gave Dr. ADOLPHE ABRAHAM'S his opportunity of studying lobar pneumonia in a large population of recruits at Aldershot. His analysis on p. 543 of the frequency of symptoms and complications has the special value arising from uniform observation, for the cases all came under his own eye. He had, unfortunately, no opportunity of making an exhaustive survey of the troops in order to define the relation between constitution and susceptibility—he was not even able to obtain, when he wanted them, the figures of the monthly strength in the Command—but he did adduce the striking fact that 62 per cent. of his total cases fell sick of pneumonia within 12 days of joining up. And this was before the influenza pandemic began. The total mortality of his 558 consecutive cases was just under 11 per cent., being markedly less than the 30 per cent. of the Johns Hopkins Hospital and the 17 per cent. of the Middlesex Hospital (1880-89), both observed on about the same number of cases, but greatly in excess of the 3.6 per cent. (quoted by Osler) among 40,000 picked men in the German army. Double pneumonia had a threefold mortality—namely 29 per cent. Herpes labialis was reinstated in its position as *signum bonum*—occurring, indeed, only in 17 per cent. of the whole, but heralding a mortality in these of little more than 4 per cent. The seventh day proved to be far the most popular day for the crisis, which is more credible than Dr. ABRAHAM'S singular confirmation of the old legend that the critical fall affects the odd day in general. Empyema was unduly frequent in the Aldershot cases, even before the influenzal epidemic which stamped it as a common and very fatal complication. Dr. ABRAHAM'S notes the large proportion of cases in which simple aspiration was sufficient to clear up the effusion.

Over and above the enrichment of the differential study of disease afforded by the circumstances of war, Sir J. ROSE BRADFORD'S experience gave him a further opportunity of great interest, that of comparing the incidence and mortality of disease in the various nations represented among the British forces. The actual attack-rate of tuberculosis was much the same among English, Canadian, and Australian contingents, whilst among the New Zealanders it was much higher. On the other hand, the resistance to tubercle displayed by the men of home origin was vastly greater than that of the Maories or of the natives of South Africa and the West Indies, men from the Dominions coming intermediately between the two extremes. No single instance of chronic or quiescent tubercle was found among an extensive series of autopsies on men of native races, although in over half the total find of pulmonary tuberculosis the lesion was quiescent. Racial variations in immunity, whatever their explanation may be, are of great interest. Obviously the material for comparison of the infectivity and virulence of disease among men of various races should be available in abundance, and the time should be approaching when analysis and classification of this experience will be available. The Lumleian lectures will make a fitting introduction to this important chapter in the medical history of the war.

Anatomical Terminology.

ANATOMY is a subject which extends far beyond the horizon of the medical student and the ordinary usage of the great majority of practitioners of medicine, so that there is nothing surprising in the fact that many of its terms have a significance for the follower of the science which they do not possess for those who only concern themselves with descriptive human anatomy. For these last they are often merely "labels," sound and fury signifying little, the evil inventions of the malevolence of terminologists. But let it be remembered that anatomy is a living science apart from medicine, the technical language of which includes its nomenclature, and it becomes evident that this language must also be living, and must come under the laws which apparently govern all living things. It is comparable with any national tongue, subject—like that tongue—to evolution under changing circumstances, and it will only reach its final form when it becomes a dead language. Philologists would be puzzled to assign reasons above criticism for the survival of some words in a language, and for the decay of others which would appear to be suitable for retention, yet such happenings are but the common results and evidence of the gradual evolution of a tongue, and similar changes have taken place and are taking place in anatomical nomenclature. Moreover, it seems that this natural evolution cannot be changed, hurried, or replaced by artificial means. The factors which mould languages in different ways under different suns may be elusive, but they are none the less effective in their action. Both these effective agents are traceable in the different languages of anatomy. Those who are acquainted with the old literature of the subject know of many examples of descriptive labels which, at first in common use, have undergone different changes in different countries as the study became less international and more in keeping with national modes of thought. We have, in the Basle *Nomina Anatomica* (1895), a serious attempt to impose an artificial formal terminology on the world of anatomy, as if the Tower of Babel were no longer worthy of consideration. Already those who have taken it up are suggesting various changes in it, and the suggestions from different countries do not by any means coincide in their tendencies. This is not surprising, and is only on a small scale what we should expect if an attempt were made to put Volapuk in place as a substitute for all the tongues spoken to-day.

It would seem probable that the B.N.A. in its present form will fail to hold its ground, in spite of its capture of some literary strongholds, even as BARCLAY'S proposals failed a century ago. No doubt certain of the terms will survive, as some of BARCLAY'S have survived, but this will be on account of their applicability and English fitness from the evolutionary standpoint, not because they are at present on the Basle list. In our last issue Dr. CUTHBERT MORTON summed up his efforts in the cause of "simplification" of anatomical language in an interesting and entertaining paper. Once more it seems probable that this scheme will yield a few additional or alternative terms to the literature, but its ultimate fate may be that of every attempt to force the hand and influence of time. Dr. MORTON brings together, and endeavours to meet, many of the complaints urged against the ana-

tomical language of the schools. These complaints and accusations crop up from time to time, and it may be of interest to consider some of them. It is said frequently that much confusion exists between the terminologies, and valiant efforts are made to cure this confusion by adding to it; or the confusion is referred to the use (or existence) of several names for one thing. But surely one of the signs of vitality and richness in a tongue is the possession of synonyms and words with progressive differences of meaning, and the occurrence of different terms in anatomical nomenclature is usually an indication of increasing and widening knowledge, and a necessary accompaniment of the effort towards perfection which is the keynote of evolution. A language which does not change with time, and increase in volume, is dead. Where several terms exist for one thing, one of them tends from its fitness to be used, and the others become secondary and, in some cases, disappear. Again, it is urged that the student is overcome by the difficulty of the labels that he must acquire. Teachers of experience deny this altogether, and hold that he has no more relative difficulty in acquiring the terms of anatomy than in learning the technical words used in the half-dozen games which he plays. It may be pointed out, moreover, that successful teachers of anatomy are not formal in their methods, for pedantry and formality are closely associated, and neither makes for inspiring teaching.

Confusion in the use of terms of position is another evil laid to the charge of the present nomenclature, and laid there unjustly, for in practice no confusion arises when the terms are used by anatomists, and if confusion is present in the student's mind it must be referred to want of instruction in his early days, not to inherent defect in the system of nomenclature. All who teach changing classes must have seen the limitations imposed on students by their ignorance of dead tongues which still live in their widespread influence, and when Dr. MORTON, for instance, describes the student as overcome by the complexity of the labels to be remembered, the blame may really lie, not on the anatomical terms, but on the faulty education of the student which does not enable him to make use of the information furnished by those terms. It would be as reasonable to refer the misuse of words by the illiterate to shortcomings in the English language itself. Most of the forms found in anatomical works of to-day are relics of that time when Latin was the common tongue in which all learned books were written. Latin and Greek words of this sort have been adopted into English; we talk of the biceps, the extensors, the larynx, the trachea, and so on, and these names seem to us almost as English. Many of the names given to muscles are used as nouns, whereas they started in life as adjectives. Greek and Latin terms which have come through the evolutionary mill are becoming anglicised, and it would probably be impossible to uproot them even if it were desirable to do so. But the use of Latin to-day is on a different footing. It may have international value, although this is probably overestimated; those who are in the habit of reading foreign literature have no difficulty in fitting the English equivalent to the foreign term, and it seems unnecessary to introduce a third class to stand between them.

Respiration and Fitness.

THE application of physiological knowledge to practical purposes has probably nowhere been more useful than with regard to the principles of respiration; prolonged storage of cereals has been rendered possible by conditions which make respiration impossible for the destructive weevil; caisson disease has ceased to be an unpreventable accident since the principles underlying the absorption of gases by the blood were employed to illuminate its mystery; while for the construction of mine rescue apparatus a grasp of these principles is fundamental. Nothing creates a stronger appeal to humanity than news that owing to a colliery explosion a number of men are incarcerated in the workings, dependent on the immediate exertions of others for their release. Volunteers are always ready to risk death in the attempt, and many noble lives have thus been lost. Science teaches that no attempt should be made unless the rescuers (1) are suitably protected against the dangers they must face, dangers associated with the poisonous atmosphere they must enter; and (2) are physically fit to undertake the endeavour. A Committee appointed by the Department of Scientific and Industrial Research to consider mine rescue apparatus in a first report¹ issued in 1918 laid down certain stringent requirements based on physiological principles. This Committee has continued its work, and in a second report² recently issued shows how these requirements can be fulfilled. The report deals in succession with the two points mentioned above. The various types of rescue apparatus are discussed, and the compressed oxygen apparatus, designed by Dr. HENRY BRIGGS, a member of the Committee, is carefully described. The underlying principles are the same as in all other types; oxygen is supplied to the wearer from a cylinder he carries, and the carbon dioxide he exhales is absorbed by caustic potash. The apparatus cannot be explained with justice without entering into technical details of construction, and the reader should refer to the report itself to appreciate the advantages which belong to the BRIGGS apparatus; it is enough here to say that it reflects credit on its designer and fulfils the necessary requirements.

Not the least interesting part of the report is that dealing with physical fitness. Here we trace the scientific mind of Dr. J. S. HALDANE, a member of the Committee, speaking on a subject of which he is the accepted master. A remarkably clear and concise summary is given of the processes of respiration; the way in which the pressure of carbon dioxide in the blood acts independently of the oxygen pressure is emphasised; and attention is drawn to the different and independent action of oxygen-want and carbon dioxide excess in stimulating respiration. Evidence is quoted (a) to show that while in an ordinary person diffusion of gases through the pulmonary epithelium will explain the access of oxygen to the blood, "the physical laws of diffusion do not explain the phenomena of blood-oxygenation when the subject is making a special demand on oxygen-supply" either because he is doing physical work or because, as airman or mountaineer, he is breathing rarefied air; and (b) in support of "the view that the epithelium

is not a mere porous diaphragm, but that the living cells from which it is built possess the faculty—which they exercise at need—of secreting oxygen from the air and of handing it forward at enhanced pressure to the blood." An interesting and new point now emerged—men in good physical training, such as practical miners, were found to possess this power of secreting oxygen from the air.

"Hence, in men who are accustomed to muscular exertion, there is no deficiency of oxygen in the arterial blood when ordinary air is breathed until exertion is pushed to the utmost. For this reason they also receive no benefit from breathing air enriched with oxygen. On the other hand, in men who are not accustomed to muscular exertion, the epithelium fails to pass in the proper supply of oxygen unless the diffusion pressure of oxygen is raised in the alveolar air by the enriched inspired air. Hence these persons benefit by enrichment of the air with oxygen. It is evident that the physiological response of a man to oxygen during muscular exertion furnishes an interesting test of whether or not he is in good training as regards his lungs. Physiological fitness depends not only on the lungs, but also on ready adaptation of the circulation, muscles, nervous system, &c., to whatever exertions are required. In ordinary cases, however, lung fitness is an accompaniment of general physical fitness, and may therefore be taken as a measure of it."

We have quoted Dr. HALDANE'S ingenious reasoning at some length, as it is apparently at variance with the views of Mr. J. BARCROFT, given in his own words in our issue of last week. Mr. BARCROFT, it will be remembered, supported his thesis by exact and quite heroic experiment on himself; but we do not know whether Dr. HALDANE would admit that he was in good physical training at the time of his sojourn in the glass-cell. Based upon the reasoning quoted above, Dr. HALDANE has evolved a method of testing physical fitness which has been used for airmen, and should also be applicable to members of a mine rescue brigade. The method, described in an appendix by Dr. BRIGGS, should be submitted to further tests, for if its value be confirmed it will be useful in other fields; for example, to test the capacity of athletes to endure the strain of strenuous and prolonged exertion, say for a contested boat-race. A further instance of the practical value of the research carried out is to be found in an estimate, contained in the report, of the most energy-saving rate of walking—a matter of importance to the economical movement of infantry. "Like a steamer or an airship, a man has a most economical speed at which he goes furthest per litre of oxygen or per pound of food." The investigation revealed that when carrying a load of 43 lb., the weight of a rescue apparatus, the most economical speed for certain subjects was 3 miles an hour and for others 4 miles; the subjects, however, were walking along an even surface, and "under the conditions obtaining in the mine we judge that rate to be about 2½ miles per hour when travelling a flat road and carrying a rescue apparatus." The speed fixed may be compared with that stated by AMAR,³ who places the most economical rate of walking along a flat surface at 2·8 miles per hour, but considers that if a weight of about 45 lb. is being carried the pace should be slowed down to 2·6 miles. It can now be gathered that the research published in this report is of first-rate importance; the work is still being continued, and further valuable results may be expected.

Annotations.

"Ne quid nimis."

NYSTAGMUS AND ILLUMINATION.

THE getting of coal from deep measures, upon which, as is being so forcibly impressed upon us this month, modern life depends, was rendered possible by Newcomen's steam engine invented in 1712 for pumping out water-logged mines. Then Watt improved the invention for use in mines and elsewhere. Forthwith the working of deep coal measures became practical, and industrial expansion a possibility; but all was for a moment checked by danger to life and limb from explosions. Another invention followed, the Davy lamp; the public owe it much, for through its use coal has been got which otherwise must have been left in situ. But for the miner this lamp has been a mixed blessing. It has carried him deeper and deeper into the earth into places fraught with danger; it condemned him to asthma until ventilation came to his rescue; it has limited his illumination and afflicted him with nystagmus. This latter disease has received considerable attention of late years. An excellent paper on its economic aspect was read at the Brussels Congress of the Royal Institute of Public Health by Dr. T. L. Llewellyn, an expert authority on the subject to whom the miner owes much for his steady insistence on bringing the facts forward. This paper appeared in the *Colliery Guardian* of June 4th, and has now been made accessible to medical readers in the current number of the *Journal of State Medicine*. The prevalence and distribution of the disorder have become known owing to its inclusion among diseases for which compensation must be paid. Its prevalence discloses that 6000 miners in England and Wales are disabled on its account each year; its distribution establishes that the disease is unknown in metalliferous mines; that among coal-miners only coal-getters are affected, and only coal-getters in mines where safety lamps are used. The disease is not confined to the United Kingdom, but prevails among miners in Germany, Belgium, and the North of France, whereas in the United States, notwithstanding inquiry,¹ the disease does not appear to be prevalent.

The symptoms of the disease are now accepted; the distressing psychology they give rise to is becoming recognised, but the pathology remains obscure. Fortunately the distribution of cases establishes clearly the relation the disease bears to inadequate illumination and points to the means necessary for prevention. The difficulty with the safety lamp is that the gauze around the light cuts off many rays, and the illumination becomes less and less as work proceeds and coal-dust collects on and blocks up the mesh of the gauze. Dr. Llewellyn, who has measured the light in mines, calculates that "the amount of light acting on the retina may be so small an illumination as only 0.0018, or roughly 1/2000th part of a foot-candle. Up to 1914 over 90 per cent. of the safety lamps in use gave less than 0.5 c.p. at the coal face." A standard illumination of 0.1 foot-candle over the whole working area is called for, and illustrations are given showing the advantages gained through whitewashing and stone-dusting the roads. The cost to the mining industry in compensation paid and loss of coal output is estimated at over 1 million pounds a year; nor does the harm stop there, since the loss of coal affects other industries, and the direct loss to the nation approximates at 1d. per ton of coal raised.

At the same Congress at which this valuable paper was presented Dr. F. Shufflebotham, another well-known writer on this disease, when putting forward a case for the science of industrial medicine, claimed that although miners' nystagmus was the commonest occupational disease known to medical science, it was only one of the several occupational diseases affecting miners, and only one of many disabling conditions at

present hardly recognised by the medical profession as affecting the general working population. Dr. Llewellyn states that steps are being taken to discover and introduce more effective and equally safe illumination for fiery mines. Necessity is as much the mother of invention now as when Newcomen invented the steam pump. Necessity is surely present in this case, and we hope that in the near future the problem will be solved. Then miners' nystagmus will disappear, as miners' asthma has already done. Relief from disease and danger may, as Professor E. L. Collis suggested last week in a letter to the *Times*, go hand in hand with a cessation of the fretfulness that threatens to paralyse industry.

WORK OF THE GOVERNMENT LABORATORY.

THERE has evidently been heavy pressure upon the staff of the Government Laboratory during the year ended March 31st, 1920, judging from the details given in the annual report just issued and signed by Sir James J. Dobbie, the principal. The returns constitute, in fact, a record. The total number of samples examined in the course of the year, including those dealt with at the outport chemical stations, was 368,898, as compared with 289,180 in the preceding year, an increase of nearly 80,000. The examinations represent therefore the passing through the laboratories and stations of over 1000 samples a day. The number examined at the Central Laboratory alone (Clement's Inn) amounted to 199,388, against 184,392, an increase of approximately 15,000. As is stated in the Appendix, the principal increases are due to goods liable to customs duty, such as wines, sugar, tea, and cocoa preparations, and the volume of work here seems to be a sure indication of the revival of trade after the return to peace conditions. Conversely, large decreases are shown in the samples submitted by such Government Departments as the Admiralty, Air Ministry, and the War Department. The report shows a deterioration in the quality of tea, since of 16,562 samples examined 6695 were reported against, or 40 per cent. of those examined. It is interesting to note that tea is examined at the port of entry by tea inspectors, and doubtful samples requiring a more complete examination than is possible by these inspectors are sent to the Central Laboratory. The increase (representing a much larger return than in pre-war times) is attributed again to a revival of trade, the tea imported last year amounting to over 500 million pounds, as compared with about 370 millions in the year ended March 31st, 1914. Restricted times in regard to the sale of alcoholic drinks may have some bearing upon this increase in tea consumption. By far the greater part of the samples rejected was owing to the presence, it is stated, of foreign matter accidentally swept up with the tea, and not to intentional adulteration. On the whole, therefore, the tea supplies were satisfactory, and indeed, considering the difficulties of the situation, the imported food commodities in general approached quite a good standard. Passing to the control exercised by the Government Laboratory over the work of the public analysts of the country under the Sale of Food and Drugs Acts, in the majority of referred cases (121 samples in all) the analyst's conclusions were upheld. The most important cases were as follows:—

Butter.—One sample contained foreign fat and one excess of water, as alleged by the public analyst.

Vinegar.—Both samples consisted of artificial vinegar, as alleged.

Cream of tartar.—The results agreed with those of the public analyst, who had found an excessive quantity of lead in the samples.

Beer.—The samples were referred by magistrates in connexion with proceedings under the Beer (Prices and Description) Order, 1919. In one case the original gravity differed from that found by the public analyst. In the remaining seven cases there was no information as to the finding of the public analyst.

Whisky and gin.—The point in dispute in the case of all the samples was the alcoholic strength; but it is not known whether or not the results were in agreement with those of the public analyst.

¹ Miners' Nystagmus, F. L. Hoffman. 1916. Washington.

In the case of ginger alleged to contain spent ginger, the results did not agree with those of the public analyst.

In the case of canned peas alleged to contain copper, camphorated oil alleged to be deficient in camphor, mustard alleged to contain foreign starch, and bicarbonate of soda alleged to contain arsenic, the results agreed with those found by the public analyst.

In the 89 cases of milk samples in which certificates were issued the charges were as follows: in 26 cases, added water; 45, abstraction of fat; 6, added water and abstraction of fat; 2, presence of preservatives; and 10, presence of dirt. In 7 cases the results were not in agreement with those of the public analyst.

The smooth working of these Acts must have been much disturbed through the period of the war, inasmuch as regulations varied from time to time in regard to the constitutional requirements of certain foods, in accordance with the regulations issued by the Food Control Board. But the pleasing indications of this report are that we are steadily approaching normal conditions again in regard to the "nature, substance, and quality demanded" of the commodities concerned.

ACUTE DIFFUSE PERITONITIS.

In a recent issue of the *Journal of the Royal Army Medical Corps* Major Basil Hughes, R.A.M.C., (T.F.), describes a treatment for acute diffuse peritonitis which in his hands has saved 20 out of 21 serious cases. The peritoneum left to itself can deal with infection if not too massive, but it is hampered by distension of the intestine which restricts its blood-supply, while vomiting reduces the fluid available to form curative exudations. Major Hughes relieves the condition by whatever operation is required, with as little disturbance as possible to the peritoneum and a minimum of drainage. The subsequent course of the patients is almost regular, and they do not have distended intestines. Subcutaneous saline, 10 pints in 24 hours, is given for two days, and is then reduced to five pints until the vomiting, which has gradually been becoming less frequent and clearer in colour, ceases on the fourth or fifth day. Morphia, $\frac{1}{4}$ gr. every eight hours, and atropine, $\frac{1}{100}$ gr. every 12 hours, for the first three days, have "splinted" the intestine. Copious drinks of water containing sodium bicarbonate and citrate, given from the beginning to wash out the stomach and allay thirst, have secured by the third day free diuresis. Flatus is passed on the third, a foul stool probably on the fourth day. Glucose is given all the time per rectum. When vomiting ceases food is given very gradually by the mouth. Castor oil on the tenth day, and after that diet may be cautiously increased. Illustrative details are given in the article.

A PIONEER IN SPIROMETRY.

Spirometry, or the measurement of vital capacity, has gone through many vicissitudes since its introduction at Brompton Hospital by Dr. John Hutchinson in the early part of last century. Professor G. Dreyer dedicates his recent exact study¹ of the use of this measurement in assessing physical fitness to the memory of this Dr. Hutchinson, of whom the following biographical details are available. John Hutchinson was the only son of James Hutchinson, of Ryton, near Newcastle-on-Tyne. He was born in 1811 and received the more important part of his education at University College, London, then recently established to meet the needs of students debarred by theological tests from attending the older universities. Sir Charles Bell had been teaching anatomy in London since 1806, and his studies of the nervous system and its relation to respiratory movement resulted in his appointment as professor of physiology at the College. Dr. Dionysius Lardner, the versatile scientific writer and encyclopædist, being professor in natural philosophy and astronomy. These were John Hutchinson's teachers. He was not only a hard-working student, but soon became a teacher, lecturing first at the various metropolitan institutions and later in his native town. He was accustomed to visit the coal mines

and to study the common causes of accident. He was elected M.R.C.S. in 1836, and undertook work at the Southampton Dispensary, Leigh-street, London, but his interests centred in scientific rather than clinical medicine. He made numerous experiments on the conducting powers, dryness, and resistance to the progress of fire of materials used in building houses, and published a work on the subject in 1843. In 1842 he was elected a Fellow of the newly established Statistical Society. His knowledge of coal gases led him to adapt the principle of the gasometer to measure the quantity of gases used in respiration. He made observations on nearly 4000 people, and tabulated the results according to height. He also used a mercurial gauge to measure the inspiratory and expiratory pressure, and tabulated the results according to professional or industrial occupation. He communicated papers embodying all these tables to the Society of Arts and to the *Quarterly Journal* of the Statistical Society of London in 1844, publishing his results later in a booklet entitled "The Spirometer" (1852). After his appointment to the position of assistant physician to the Brompton Hospital he began to measure the vital capacity of the patients suffering from chest trouble, and urged the general use of the spirometer in the detection of early or threatened phthisis. He was awarded the degree of M.D. by the University of Giessen in 1846. He communicated a more extended description of his studies in respiration to the Medico-Chirurgical Society of London in 1847, which was translated into German and published as a separate pamphlet in 1849. His other contributions included papers on heat, malaria, and ventilation to the *Journal of Public Health* (1848) and an article on the thorax for Todd's *Encyclopædia of Anatomy and Physiology*. He gave valuable evidence before a Select Committee of the House of Lords on the Prevention of Accidents in Coal Mines. He must have been a versatile man, for we read: "He was also gifted with an exquisite ear for music; his execution on the violin was masterly. He had a great ability as a draughtsman. He sculptured admirably in bas-relief and painted in oils." His restless spirit was constantly searching for new outlets. Soon after the discovery in 1851 of gold deposits in Australia he left England and began to make extensive collections of various gold-bearing rocks which he intended should become the property of the British Museum, but for some unknown cause they found some other destination. Of his career in Victoria for the next eight years nothing is known, and it does not appear that he made any further contribution to science. In 1861 he travelled to the Fiji Islands, dying there in July of that year.

"APPARENTLY DEAD."

THIS is the title of an interesting note by Mr. W. G. Spencer in the September issue of *Medical Science*. He cites a case described¹ by E. Rautenberg which would have been buried alive, had it not chanced that the coffin was reopened for purposes of identification. The woman had been reduced to the state of a hibernating animal by an overdose of morphia and by cold. The doctor who examined her in the mortuary applied only one special test, that of dropping sealing-wax on the skin. He made no note of the state of the pupils, which were subsequently found contracted. The details are as follows:—

On Oct. 27th, 1919, a hospital nurse, aged 23, bought from an apothecary in Charlottenburg for 20 marks 50 c.cm. of a 3.5 per cent. solution of morphine, and 10 powders each containing 0.5 g. of veronal. She then went into the Grönwald, and about 4 P.M. swallowed about 1.7 g. of morphine and 5 g. of veronal. She wandered about as in a dream until she lost consciousness. The weather was cold, the temperature during the night being 1–3° C., and wet.

When she was found the next day, she was assumed to be dead and was taken to a mortuary, where the medical officer of the district examined her. The body had a deathly pallor; there was an absence of pulse, of respiratory movement, of the heart sounds, and of all reflexes. There was partial

¹ The Assessment of Physical Fitness. Cassell and Co. 1920. 10s.

¹ Ein bemerkenswerter Fall von Scheintod. Deutsche med. Wchnschr., 1919, 45, 1277.

stiffness of the trunk and limbs, and it was assumed that rigor mortis was as yet incomplete. There was no reaction to sealing-wax dropped on the skin. There is no mention of the state of the pupils. After the examination, the body was put in a coffin, still in the wet clothes. Fourteen hours later, on October 29th, the coffin was reopened in order that a lawyer might identify the body. The undertaker's men then noted that the cheeks were coloured blue and that there was a slight movement of the head. The same medical officer was again called and now heard faint heart sounds, but there was still an absence of a pulse and of respiratory movement. The patient was then moved to a hospital, when at 10 A.M. on the 29th—i.e. 42 hours after the poison had been swallowed—it was found that the trunk and limbs were partially stiff, that she was unconscious, and that there was no reaction to stimuli. The double heart sound could be heard over the sternum, the heart beating 30-40 a minute; signs of breathing and of a pulse were absent. Both pupils were markedly contracted. The skin and lips were deadly pale, but the cheeks were bluish (*leicht cyanotisch*). The stomach wash contained morphine; the urine drawn off from the bladder, besides albumin and casts, also contained a small quantity of morphine. Under active treatment for morphine poisoning the stiffness of the limbs began to pass off in two hours; consciousness began to be regained on the 30th. On Nov. 3rd the patient was convalescent and the urine free from albumin. No pneumonia or other complication supervened.

Mr. Spencer aptly quotes Marshall Hall's saying that "hibernation is, in every respect, but the parallel of ordinary sleep, varying only in force and duration."

NOCARDIASIS CUTIS RESEMBLING SPOROTRICHOSIS.

Dr. William H. Guy, of Pittsburgh, reports¹ a case which clinically resembled sporotrichosis, of which over 200 proved cases have been recorded since Schenk published his paper in 1898 on Refractory Subcutaneous Abscesses caused by a Fungus possibly related to the Sporotricha.

The patient was a coal-miner, aged 51, who presented a number of inflammatory nodules and indurated ulcers extending from the base of the left thumb to a point slightly above the bend of the elbow. On inoculation of various culture-media with the contents of one of the unbroken lesions several greyish-white pinhead-sized colonies appeared, which were found to consist of a mass of tangled threads bearing small granules. The organism was therefore identified with that which was originally isolated by Nocard from the superficial abscesses of cattle suffering from farcy. When first seen the patient was diagnosed as a case of sporotrichosis and was given a saturated solution of iodide of potassium. Apart from simple protective dressings, nothing else was done, and uninterrupted recovery took place.

A review of the recent literature on nocardiasis is appended, including the paper by Dr. J. B. Christopher-son and Major R. G. Archibald in THE LANCET² on primary nocardiasis of the lacrymal gland.

VETERINARY SURGEON AS MEAT INSPECTOR.

THE want of a proper and uniform system of meat inspection in this country is being increasingly felt, while little is being done to select for the position of meat inspector the man most likely to be fitted for it—namely, the veterinary surgeon. His collegiate training includes both a special course and a special examination in meat inspection, and no one knows better the condition and appearance of the organs of animals in health and disease. The matter came before the largely attended representative meeting of the members of the Royal, Southern, and South-Eastern Counties Veterinary Medical Societies, held in London last week, when Mr. James Hayhurst, superintendent and veterinary inspector of the Metropolitan Cattle Market, Islington, read a paper on "The Duties of a Veterinary Meat Inspector," in which he particularly emphasised that in England only the larger towns had any pretence of meat inspection, and that in many places a butcher might, if he liked, offer for sale diseased or unsound meat with little risk of discovery. He drew attention, too, to the necessity for public

abattoirs as against private slaughter-houses, and many other points in which Great Britain lags behind other countries in respect to the inspection of foodstuffs. At the termination of the discussion which followed Professor F. Hobday proposed the following resolution, which was carried unanimously, to be sent to heads of corporations and local authorities:—

That in the opinion of this meeting it is essential, for the protection of the public health, that a proper system of meat inspection be arranged; and that the veterinary surgeon, by virtue of his training in the diseases of animals and their flesh, was the best authority to be utilised for the purpose. Also that if public slaughter-houses were erected the cruelty to animals which sometimes occurred in private slaughter-houses would be prevented, and young children would be debarred from being within its precincts.

If the inspection of meat for human food is to be thorough and reliable it must be done by the scientifically trained man.

DOUBLING OF THE SPINAL CORD.

Dr. Benjamin Lipshutz¹ reports a rare variation in the anatomy of the spinal cord encountered during the regular laboratory work in the dissecting-rooms of the Daniel Brough Institute of Anatomy at the Jefferson Medical College. No clinical history of the case was available. The anomaly, which was found in the body of an adult male aged 35, consisted in a bifurcation of the spinal cord beginning at the twelfth thoracic vertebra and extending to the caudal limit of the spinal cord so as to form two independent symmetrical halves. The caudal limit of each half was at the level of the cephalic border of the first sacral vertebra. The conus medullaris of each half was independent, union taking place at the level of the third sacral vertebra into a single large filum terminale which was attached to the dorsal surface of the first segment of the coccyx. The cervical and thoracic portions of the cord were normal. Another anomaly was present in the form of an hour-glass shaped band of dura in the sagittal plane projecting between the two halves of the cord. There was also a number of small, flattened calcareous plaques adherent to the spinal arachnoid. Duplication of the spinal cord is a rare occurrence, only ten undoubted cases having been collected by Bruce, McDonald, and Pirie in 1905. The division usually occurs in the lumbar or lower thoracic segments of the cord. Other abnormalities, though absent in the present case, are frequently present, such as spina bifida, meningocele, and cutaneous or bony malformations.

MALARIA INVESTIGATIONS IN THE MALAY STATES.

SOME years ago a Malaria Bureau was established in the Federated Malay States, but its operations in the past seem to have been hindered by the inadequacy of its staff. It is locally admitted that the malariology of the country is very incomplete, but efforts are now in progress to make good this defect. Owing to the incompleteness of the available information it has been necessary hitherto to exercise great caution in accepting any generalised conclusions. From a recently published report by Dr. H. P. Hacker² we gather that efforts are at present being made to place the malariology of Malaya on a firm basis, and that now the main object of the work of the Malaria Bureau will be to collect full and accurate data concerning the disease and its various factors throughout the country. No general conclusions will be issued by the Bureau until they can be based upon an incontrovertible basis of facts. With a view to carry out the work we understand that the staff of workers is to be increased, and that from time to time reports will be issued giving details of the information as it is collected. These reports, Dr. Hacker believes, will become objects of reference and may assist other workers in arriving at a more uniform theory and practice of malaria prevention and treatment. In his

¹ Archives of Neurology and Psychiatry, July, 1920.

² THE LANCET, 1918, ii., 847.

recently published report Dr. Hacker calls attention to the insufficiency of our knowledge of the relative malaria-carrying properties of the various species of anophelines, and the conditions which control these properties. The pathogenicity, too, of jungle species of these mosquitoes is practically an untouched subject, and stands in urgent need of coördinated research. In the Malay States the most important carrier of the malaria infection seems to be *A. maculatus*, which is found usually in the hilly country; the less dangerous, *A. aconitus* and *A. fuliginosus*, are found in open swampy regions, and *A. umbrosus* in low-lying jungle. There are, of course, many other anophelines in Malaya, but these are among the species that have chiefly to be considered. The felling of jungle and the opening up of wooded ravines have been advocated by some authorities as an antimalaria measure. Experience, however, in the Malay States has shown that such operations require to be carried out with extreme caution. *A. maculatus* does not breed under the shade of secondary growth of vegetation or jungle, but as soon as a ravine is cleared *A. maculatus* appears and begins to breed rapidly, while the less dangerous jungle-frequenting mosquitoes disappear. If the opening up of hill jungle be necessary for the development of a place, Dr. Hacker insists that attempts should be made to keep ravines, which contain practically all the water and therefore all the breeding-places, under the original jungle and thus prevent the access of the dangerous *A. maculatus*. This is only one of the points touched upon by Dr. Hacker in his present report, there are also others of equal interest which can be usefully studied at first hand by those concerned with the problems of malaria. The proposed collection and publication of carefully verified data concerning the disease in the Federated Malay States is likely, in our opinion, to give valuable assistance in the solution of some of the still outstanding problems connected with malaria, a disease which impedes the economic development of many of our colonies and dependencies.

EYE-STRAIN IN KINEMAS.

In response to an inquiry from the London County Council as to the possible causes of eye-strain in kinemas and the best means of removing them the committee of the Illuminating Engineering Society has now issued an interim report¹ which has behind it the authority not only of that society but also of the Council of British Ophthalmologists and of the Physiological Society, both of which bodies were represented on the committee. The point chiefly dealt with in this interim report is the proximity of seats to the screens. Experience shows that discomfort arises largely through effort involved in raising the eyes to observe pictures presented at an unduly high level, and the recommendation is made that the angle of elevation measured to the top of the picture should not exceed 35°. The kinema headache would appear to have this much in common with the "Academy headache," that both are related to fatigue of the elevator muscles of the eye. A limit to the lateral angle of view of 25° is also recommended. Another definite recommendation is that the illumination of the auditorium, which should be nowhere less than one-fortieth of a foot candle, should gradually be increased from the front to the back of the auditorium. A still more important point is that a definite rule should be enforced that no unscreened source of light should be visible to the observer from any seat in the theatre while looking towards the picture. Other matters touched on but left to be dealt with more fully in future reports are the different varieties of "flicker," film, and mechanical defects, and a possible standard of minimum brightness for the screen. The only reservation made by any members of the committee is by those representing the kinema industry, who draw attention to the absence of evidence of serious injury by eye-strain, and are of opinion that where the recommendation concerning seating would entail serious financial hardship there is no justification for the

imposition of the rule recommended. Our own opinion is that here is a matter in which the interests of the public, although not vital, are yet of sufficient importance to justify State or municipal protection.

SYPHILIS SIMULATING SYRINGOMYELIA.

Dr. Walther Blumenthal,¹ of Coblenz, records the following instructive case. A lieutenant, aged 22, was exposed to infection in the beginning of September, and developed a chancre three weeks later, which cleared up under treatment with neosalvarsan. At the end of October he complained of both hands feeling dead. On examination dissociated sensory paralysis was found in both hands; in the right more than in the left, corresponding to a small isolated focus in the seventh cervical segment in the neighbourhood of the central canal. There was slight disturbance of tactile sensation in the first, second, and third fingers up to the middle line of the third finger, and perception of pain, heat, and cold was almost completely lost in these fingers. Examination of the rest of the nervous system, including the reflexes, cranial nerves, and fundi revealed nothing abnormal. Lumbar puncture was not performed. Although the initial lesion had appeared only five weeks previously and no secondary symptoms had yet developed the clinical picture suggested syphilis of the cervical cord. Energetic treatment with silver-salvarsan was instituted and the symptoms gradually subsided in the course of three months, during which other spinal-cord symptoms occurred—viz., slight inequality of the knee-jerks and abdominal reflexes—but soon disappeared.

THE METRIC SYSTEM IN THE BALANCE.

In October, 1916, a Committee was appointed to consider and report upon the advisability or otherwise of the compulsory adoption of the Metric System of Weights and Measures in the United Kingdom. This Committee, presided over by Sir Joseph J. Thomson, was appointed by the Conjoint Board of Scientific Societies, and a report was first prepared in June, 1917; delay, however, ensued through fresh considerations arising, and the report has only now been published. The terms of reference were wide enough to remove the question out of the purely academic sphere and to make it necessary for the Committee to consider the effects in common life as well as in technical manufactures and industries. Briefly, its recommendations covering scientific ground in a wide sense amount to the following:—

That the British system of units of weights and measures be retained in general use in the United Kingdom.

That a definite movement towards compiling statistics in metric units should be set on foot. (This refers chiefly to maps and plans and contours, which, it is held, should be shown in metres and not in feet.)

That while it is not proposed to abolish such units as the mile, the yard, the foot, and the inch, distances should be expressed in miles and decimals of a mile, decimals of a foot, but not in any complex of miles and yards, feet, and inches; that railway charges should similarly be calculated in tons or in pounds, but not in hundredweights, quarters, and pounds, and so on.

That according to the above principle the pole, furlong, and league be abolished, as well as the square rod or perch and rood, all areas of land being measured in acres and decimals, or in square feet for small plots. Similarly, the abolition of the grain, dram, stone, quarter, and hundredweight of 112 pounds is recommended, and the complete abolition of apothecaries' weight.

That the use of the gallon as a general standard of capacity be retained, subdivided for retail use into quarts and pints; that the peck, bushel, quarter, chaldron, and barrel be abolished and measure by weight substituted.

That the use of the metric system be made compulsory with as little delay as possible in the whole trade in fine chemical and drugs, and in all specifications and prescriptions relating to such products.

That no change in the existing system of British coinage be attempted in present circumstances.

With few exceptions the report appears to have been considered favourably by the scientific societies and financial authorities, the former urging the use of the metric system in all scientific work and its introduction into industries, especially those of a complicated kind involving scientific and technical processes. That medicine has been singled out for special treatment by a non-medical committee of reference is a testimony to the

¹ The Illuminating Engineer, June, 1920.

¹ Deutsche medizinische Wochenschrift, August 12th, 1920.

exactness of our discipline and to the open-mindedness of its votaries. The Council of the Royal Society of Medicine strongly endorses the proposal to adopt the metric system in connexion with medical science, and the Council of the Royal College of Surgeons expressed its approval of the recommendations. It will be seen that these recommendations do not bid for uniformity and, if adopted, would leave medicine still with a more or less mixed system of standards. But the use of the metric system in prescribing must result in its adoption for the weight and dimensions of the human body; and the rest would soon follow. It is significant that the chairman, Sir J. J. Thomson, has not signed the report, nor have M. le Duc de Broglie and Mr. Charles P. Sparks. The signatories are Mr. H. Wilson Fox, M.P.; Sir Robert Hadfield, F.R.S.; Mr. A. R. Hinks, F.R.S. (secretary); Sir Philip Magnus, M.P.; the late Professor J. Perry, F.R.S.; Professor W. Cawthorne Unwin, M.Inst.C.E., F.R.S.; and Professor W. W. Watts, F.R.S., secretary to the Conjoint Board of Scientific Societies.

A MILITARY M.O.H. GROUP.

WITHIN the Society of Medical Officers of Health a group is being formed by those members who are specially interested in naval, military, and air-force hygiene. Its formation has the approval and support of the official heads of the medical departments of the Navy, Army, and Air Force. The group will be drawn from the three Services and from their auxiliary forces, membership being confined to medical men who hold, or who have held, sanitary appointments in any of these Services and to those who are in the possession of a diploma in sanitary science, public health, or State medicine. The object of the group is to provide an opportunity for present and past officers of the Services to meet and discuss papers dealing with subjects of common interest as well as to make more close the liaison between officers in the Services and medical men carrying out similar work under civil conditions. Nothing but good can come of such free and informal exchange of views between those who have seen hygienic practice under all manner of conditions, and the deliberations of the group will be watched with attention by those officially responsible for public health. All medical men eligible for membership are invited to communicate with Major W. N. W. Kennedy, O.B.E., Town Hall, Croydon, acting honorary secretary. The subscription to the society, including membership of the group, is £1 1s. per annum, which entitles members to receive a copy of *Public Health* each month. The first meeting of the group will be held on Friday, Sept. 24th, at 4.15 P.M., when officers will be appointed, and Brigadier-General W. W. O. Beveridge, director of hygiene at the War Office, will read a paper on Disinfection in the Field.

ATTENTION is directed to the notice in our news columns of a course of post-graduate study for general practitioners at St. Andrews, under the direction of Sir James Mackenzie.

THE constitution of the War Office Departmental Committee to inquire into the expert knowledge derived from the experiences of the late war in regard to shell shock, over which, as we announced last week, Lord Southborough presides, is as follows, the departments which each member represents being added in parentheses: Temporary Surgeon-Lieutenant Thomas Beaton (Admiralty), Dr. J. L. Birley (Air Ministry), Dr. H. J. Bond (Board of Control), Dr. Maurice Craig (Ministry of Pensions), Wing-Commander M. W. Flack or Wing-Commander J. McIntyre (Air Ministry), Dr. H. W. Kaye (Ministry of Pensions), Dr. Hamilton C. Marr (Board of Control for Scotland), Surgeon-Commander E. T. Meagher (Admiralty), Brigadier-General J. G. S. Mellor, Sir Frederick W. Mott, F.R.S., Major A. D. Stirling and Dr. W. Aldren Turner (Army Medical Department), Mr. Stephen Walsh, M.P., Major W. Waring, M.P., with Major W. R. Galwey (secretary).

PUBLIC HEALTH IN SOVIET RUSSIA.

By L. HADEN GUEST, M.C., M.R.C.S. ENG., L.C.C.
SECRETARY AND PHYSICIAN TO THE BRITISH LABOUR DELEGATION.

II.—THE MEDICAL SERVICES.

THE work of dealing with epidemic diseases in Russia has been carried out by a nationalisation and centralisation of all public health and medical work. The Commissariat of Public Health came into existence at the end of 1917, and controls the services of the army and navy, as well as that for the civilian population. The work of the department is divided into (1) medical and (2) sanitary, (3) a temporary anti-epidemic service. All medical services of any kind whatsoever come under the control of the Commissariat. In theory all medical and dental attendance is free, and in practice free treatment, in so far as it is available with the limited resources at the Soviet Government's disposal, is "accessible" to all free of charge. In fact, alongside of this free system the old system of private practice continues, although only some 10 or 20 doctors in Petrograd are not in the service of the Soviet Government. In Petrograd the acceptance of fees is severely frowned upon, and I heard of a physician in State employ being prosecuted by the Tribunal of the Peoples' Justice for demanding a fee of 1000 roubles, nominally £100. In our money 1000 roubles is roughly equivalent to 2s. at present rate of exchange, and will purchase in the open market 2½ lb. of bread, about eight eggs, or about a quarter of a pound of butter. In other towns the taking of fees seems to be regarded less severely. As far as I could gather all hospital or institutional treatment was free in fact.

Owing to the shortage of doctors it is usual for three, four, or more separate appointments to be held at the same time, and the doctor holding them receives a salary for each appointment. A usual monthly salary is 4000 roubles per appointment. The number of doctors in Petrograd, including army doctors, was 1300, about half of whom were women. Doctors are paid salary on a scale varying with (1) length of service, (2) specialist qualifications. Doctors also usually have rooms provided, and very frequently their meals provided also. I was told that sometimes doctors receive not only the salary for each separate appointment held in money, but also the rations for each separate appointment in kind. One doctor told me that extra bread came in useful for paying cab fares. There are a few droshkies still available in the streets; the fare for a short distance in Moscow, for instance, being 2000 or 3000 roubles. But the "isvostchniks" (drivers) prefer to be paid in kind. Small tablets of soap are a useful kind of small change to carry about.

Organisation in Petrograd.

The organisation in Petrograd consists of a central town public health service under the control of the Petrograd Health Department, who are all Communists. At the head of this is Dr. Pervouchen, who was careful to explain to me that he held his appointment, not as a doctor, but as a Communist and a representative of the workers. Under this central department are the ten districts (rayons) into which the town is divided, each district having its own health department. Sick persons able to attend as out-patients go for medical treatment to one of the town clinics, and if they do not know where to apply can get information at the district headquarters of the health department. Those needing to be visited at home send a message to the district headquarters and a doctor calls at the house. I was told that all cases requiring hospital treatment are transferred to hospital by the ambulance service under the control of the town.

I personally inspected a parade of this ambulance service, which was under the command of Dr. Haffkine (nephew of Dr. Waldemar Haffkine). The organisation was military, and the personnel consisted largely of medical students. It has been created by the Bolsheviks. This transport service, however, discharges several different functions, and provides

(a) first aid by doctors in case of accident and emergency; (b) transport of cases to hospital; (c) transport of infectious cases to hospital, and disinfection and repair in the homes of infectious cases removed to hospital. I saw myself a large number of motor ambulances and horse ambulances and one steam tram ambulance, as well as closed wagons for transport of clothing and bedding for disinfection. At the special parade which took place in the grounds of a large hospital the personnel of the corps gave a display of stretcher drill in which they were quite reasonably proficient. Mistakes and awkwardnesses were apparent, but were of exactly the same nature as those made by any ordinary field ambulance on nervous occasions. The clothing of the personnel of the corps was good, close fitting coats and breeches of leather for the majority and good boots. The heavy losses from infection suffered by doctors and sanitary personnel have made the authorities very careful of the lives of those doing this dangerous work. Doctors engaged in infectious diseases work are paid 80 per cent. more than others, and get rations on "Red Army" or highest scale. Nevertheless, 50 per cent. of doctors so employed have died from typhus and other infections. The statistics regarding number of persons employed on this first-aid and transport service in Petrograd I give as they were stated to me by Dr. Pervouchen: Doctors, 40; sanitary instructors (medical students), 36; motor ambulances and motor-cars, 104; horse vehicles (expropriated private broughams are used as well as ambulances), 189; trams, 10; steam tram, 1; sanitary wagons, 5. The cars, wagons, &c., I saw were in workmanlike condition. The horses were in reasonably good condition. The total number of personnel engaged in disinfection duties was given as 1017, which included 360 trained sanitary men to carry out disinfection and subsequently repair any damage done. This insistence on repair of damage was for the purpose of cultivating good feeling and so facilitating disinfection.

Hospitals: A New Institute of Radiology and Röntgenology.

During the height of the typhus epidemic last winter many temporary hospitals were opened for treatment of this disease. Many ordinary hospitals (about 100), however, had to be closed on account of absence of coal and wood for heating, and consequent breakdown of

speaking English and French—that whereas the discipline in the hospitals at the beginning of the Revolution was very bad, it was now "like old times."

The only other medical institutions I saw in Petrograd were a clinic for the study of defective children, in which they were specialising in rather elaborate studies of mental defect, and a "first-aid" hospital for emergency cases. All three of these were far above

FIG. 2.—The monument to Röntgen in the forecourt of the Institute. The names on the plinth are: W. C. Röntgen, C. G. Barkla, W. H. and W. L. Bragg, M. Laue, A. Sommerfeld, H. G. J. Moseley, P. Debye, M. Sklodowsky-Curie, H. Curie, H. Becquerel, E. Rutherford, W. Ramsay, W. Crookes, J. J. Thomson, P. Lenard, H. A. Lorentz, C. T. R. Wilson, Millikan, M. Planck, N. Bohr.

the average level of Russian hospitals, but I did not have an opportunity of seeing a normal hospital in Petrograd owing to the necessity for attending a tremendous military and naval review got up in honour of the Labour Delegation. The mortality of children in hospital (up to 12 years) was given as 24 per cent. The birth-rate was said to be rising rapidly. The figures of 40,000 births per annum were given for the pre-war Petrograd of 2,500,000 people, and a present number of 20,000 to 25,000 births per annum for the present Petrograd of about 1,000,000.

Arrangements in Moscow.

In Moscow the medical arrangements were rather different. Free treatment was available, but fees appeared to be paid pretty openly to doctors and dentists. And all institutions were centralised and not arranged in districts, nor was there apparently a district health organisation in addition to the central town organisation. A hospital at the Kremlin, where the chief Government offices are, was well equipped with medicines, but the resident doctors were only partly qualified. The arrangements were otherwise passable. Two town hospitals inspected were badly arranged, badly disciplined, and, in the typhus block, dangerously dirty, no disinfection and little washing having been attempted. These two hospitals were indicated to me by non-official persons as "normal" samples of Russian institutions. The beds were largely without linen and mattresses and the very poor blankets provided were dirty and insufficient. The surgical wards, however, were very much better than the medical. The doctors looked ill, half-starved, and terribly depressed. An

FIG. 1.—The new Institute of Radiology and Röntgenology in Petrograd.

water and sanitary arrangements. As, however, the population has decreased from 2,500,000 to about 1,000,000 (probably 800,000), the decrease matters less than it would have done formerly.

A new Institute of Radiology and Röntgenology (see Figs. 1 and 2) has been erected under the medical control of Dr. Nemenoff, President of the Institute. This institution combines a hospital with a scientific research department, and is publishing some of its results at present. I saw these research laboratories as well as the wards, and the work was going on quite satisfactorily except for the lack of Coolidge tubes. A special factory for repairing and remounting of X ray tubes has been erected in Petrograd in connexion with the Institute. I was told—by a junior house surgeon

eminent physician I met could not be induced to believe that England might lift the blockade and allow medical and other supplies to come through. He was a very sad, unsmiling, and bowed man. Other medical institutions seen in Moscow were much better, the special clinics lately established being on more modern lines.

Medical Service in Country Districts.

In addition to Petrograd and Moscow, I saw hospitals at Saratoff on the Volga and at Beresnaki on the Volga. The standard was not high, but it was adequate. A great effort against the odds of tremendous difficulties is being made in Russia to keep the medical service going and to improve it. Their difficulties, apart from lack of soap and medicines, lie in the failure of the supply of doctors, which has led to the temporary employment of partly qualified people for appointments needing fully qualified men or women. The medical faculties at the universities are working, but not well, and it will be some time before Russia has all the doctors she requires. The conclusion of peace will render the army doctors available, but even their services will not fill up the gap that has been made by death, war, and revolution.

The classification of medical institutions in Russia is given in the following list, which represents, however, rather the ideal than the achieved (no Russian statistics can be accepted without serious reservations):—

- (1) General clinics for areas with a population of 2000 to 3000 persons.
- (2) Special clinics for eye diseases, skin diseases, venereal diseases, &c.
- (3) First-aid institutions.
- (4) Night-duty medical service.
- (5) Visiting medical service.
- (6) (a) General hospitals for regions; (b) special hospitals (obstetric, ophthalmic, &c.) which serve whole towns and their surrounding villages.

The total number of hospitals in the republic is given as 10,000, with about 270,000 beds, 17,000 doctors, 35,000 medical assistants, and 120,000 junior medical staff. Medical arrangements for the country aim at making medical assistance available for all at a maximum distance of five versts. In pre-revolutionary Russia the distance was often 20. Progress has already been made in the direction desired, notably in the Poltava government.

The nationalisation of medical service has, of course, extended to health resorts, the places available for treatment being usually allotted by the Central Commissariat of Health, except in the case of institutions of purely local importance. During 1919, 5000 patients were so treated, and they were no longer the old-time patrons weighted with over-generous living. The distribution of patients at Lipetz in the Tambov government is given as Workers and Soviet officials, 70 per cent.; Red Army, 25 per cent.; other citizens, 5 per cent. Board, residence, and treatment are all free at these institutions.

(To be continued.)

HOUSING NOTES.

The Labour Housing Association.

THE Labour view on the shortage of houses was ventilated at Portsmouth on Sept. 4th, when the Labour Housing Association held its annual meeting. Much of Mr. Thomas's speech might have been uttered on behalf of the Ministry of Health; as when he pointed to the influence of bad housing on political unrest or advocated increased transport facilities to combat overcrowding. But the resolution condemning the Government had no constructive suggestion and criticisms of the Ministry's housing standards carried no particular weight. Some interesting figures were given by Mr. George Hicks, secretary of the Bricklayers' Union, who announced that out of 54,000 bricklayers only 7000 are engaged in house construction, while of all building trade operatives less than 10 per cent. are so occupied as compared

with 40 per cent. before the war. This is an intolerable state of things.

Building in Concrete.

Among the methods favoured by the Ministry of Health for the reduction of the cost of building is the use of alternative materials of construction to the orthodox brick and mortar. Amongst the various substitutes hollow concrete blocks are, perhaps, the favourite. A bungalow built on the Clifton-Ewart system has just been put up at Nottingham. The chimney stacks are of brick, but in later models these will, no doubt, be replaced. The rest of the skeleton is composed entirely of concrete blocks. No wood has been used except for doors and windows. The bungalow, which was built in three weeks and could by intensive work have been completed easily in half the time, contains four good-sized rooms, bathroom, and lavatory, and when the subsidy has been deducted the cost will be £300. No doubt such bungalows could be built more cheaply, as, for example, by the employment of unskilled labour. But it is premised that any attempt to cheapen housing construction will be rendered void by the interest vested in the brick. Every builder is dependent on the good-will associated with the brick, for though he might build his walls with non-union labour he would be unable to find plumbers, carpenters, or electricians to complete the work. So it comes about no one can afford either to use bricks or to do without them. In the meantime, the unskilled man remains unemployed and his children are crowded ever more and more into the insatiable slums.

Standards of Accommodation in Herefordshire.

Some time ago the Ministry of Health suggested to medical officers that the housing section of their annual reports should be issued as a separate document. Among others Dr. Herbert Jones, M.O.H. for Herefordshire Combined District, has complied, and a comprehensive survey of present housing conditions is the result. In half of the parishes more houses are needed, and the schemes submitted to the Government, even were they completed at the present day, would not meet this need. As regards the standard of accommodation, Dr. Jones would have each house built on a quarter-acre plot and to contain parlour, kitchen, wash-house, scullery, bath, and three bedrooms. By discussing the question at "women's institutes" and other organisations he has discovered a unanimous opinion in favour of both parlour and bath. The latter is wanted even where water cannot be laid on, the women being more anxious that the bath should be easily emptied than that it should be easily filled. He adds that there are old-age pensioners occupying houses larger than they need, and hints that if convenient houses—presumably with less than three bedrooms—were provided for these their present dwellings would become available to larger families.

A Tragedy at Wandsworth: No Room for the Baby.

An occasional incident of human interest serves sometimes to bring home the importance of impersonal political movements. Such an incident was provided at a London police-court, when a man was recently charged with aiding and abetting his wife, aged 28, to kill herself. The woman died, it was said, as the result of an illegal operation, and the evidence showed that her wish to avoid the birth of a child was due to her inability to find a house which would provide it with a decent home. We agree with the magistrate that a full realisation of the price which our fellow citizens are paying in suffering and disease would help considerably those who are now negotiating to find some speedier way of settling their differences and of proceeding with the rapid delivery of houses.

Annual Report, 1919, issued August 20th, 1920.

SCARLET FEVER IN MANCHESTER.—Seventy-five cases of scarlet fever were reported in Manchester last week, as against an average of 60 during the six preceding weeks. There are four cases of small-pox in the Clayton Hospital, but no new cases have been notified in Manchester during the past fortnight.

HYGIENE ON THE SEA: ACCOMMODATION FOR SEAMEN IN SHIPS OF TO-DAY.

(BY OUR SPECIAL CORRESPONDENT.)

I. THE "AQUITANIA."

THE *Aquitania*, of 45,647 tons gross (this is her sea-going loaded weight), with the black tops of her four red funnels soaring to the skies, looked huge as one approached her in the docks at Southampton. And a big ship she is—over 300 yards long, with 97-ft. beam, and a load-draught of water of 35 feet. She is fast, too, for her oil-driven turbine engines, with their 56,000 horsepower and their four screws, give her a speed of 23 knots, or 26 land miles per hour. When the Cunard Company was good enough to send me on board she was in the usual turmoil of a ship the day before going to sea, when all kinds of stores are coming on board, strangers are flocking to and fro on business, and, in spite of these strangers and the dirt they are bringing on board, every endeavour is being made to get the ship thoroughly cleaned. At such a time, seeing she is alongside a wharf with big sheds that keep the wind off her, a ship is so hot that one feels she should be taken out into the stream and anchored for a night to get aired and cool before her passengers arrive; but that is a counsel of perfection. They are many, these passengers, 750 first-, 900 second-, and some 2000 third-class, and with her officers and crew her captain has the responsibility at sea for the lives of some 4000 souls.

Comfortable Accommodation for Passengers.

The company is doing what it can to make them all as comfortable as they can afford to be. There are suites for millionaires with sitting-rooms and bedrooms, smaller cabins for the less wealthy, all in the first-class section having fixed basins and hot and cold water laid on. In the third-class there are folding wash-stands and the furniture is less magnificent, but the beds are good. For the first-class passenger there is a beautiful saloon, a grill-room, too, a magnificent smoking-room, lounges, a swimming bath, and a gymnasium. The second-class saloon is very bright and comfortable. These saloons have chairs, and that shows the company has confidence that the steadiness of the ship and the deep pile of the carpets make it certain that in no weather is there fear that the rolling of the ship will seriously incommode the passengers. Not till we come to the third saloon do we find the fixed pedestal, rotating seats that we all know at sea. There are pianos for every class of passenger.

The medical officer on duty received me, but as he was for the moment busy I was taken round the ship by the dispenser, formerly a chief sick-berth steward in the Royal Navy, and under his capable guidance I saw how the practice of hygiene is improving at sea. There are three hospitals in this great ship, and in each 12 beds. One hospital for men, with the dispensary and operating-room adjacent, and another for women; a third, distant and well isolated, is for infectious diseases. Besides the dispenser and his mate, there are two female nurses on the staff.

The System of Ventilation.

The ship is, of course, artificially ventilated. In fine or moderate weather the numerous side ports are open. There are some in dangerous positions which are fitted with Utley's patent water-excluding side lights, which permit ventilation in all weathers. But never can enough air for so many people pass naturally in and out of so large a ship. Accordingly there are everywhere between decks, in cabins, saloons, and lobbies, in bath-rooms and water-closets, trunks or conduits for forced ventilation, carrying in fresh air or exhausting the foul. And as cold air might chill the inhabitants and cause complaints there are fitted in the ship 36 thermo-tanks, which heat the air before it is introduced into the ship. The ventilation of a ship is a com-

plicated problem, and it is said on board that the currents in a ship cannot always be made with advantage to run constantly in the same direction; accordingly these thermo-tanks and their fans are fitted so that they may be driven either direct or reversed; that they may be used alternatively as supply or exhaust ventilators. This is, I think, to be regretted. Trunks are hard to clean, and an exhaust trunk is apt to accumulate some dust, and when the current is reversed some of that old dust is carried out. An epidemic of sore-throat has been attributed to this cause. Generally fresh air is supplied to cabins and passages, while lavatories, &c., have exhausts. Water-closets are in such a ship so high above the water that shore patterns are used, with a strong flush from a sanitary tank of sea water.

The Crew's Quarters.

But readers of THE LANCET will specially desire to know what improvements there are nowadays in the accommodation of the crew. The *Aquitania*, a hospital ship in the war, has since the war been completely refitted, and advantage has been taken of this opportunity to remodel all the berthing arrangements of the crew. Certainly they are very different from those the writer remembers in the *Campania* of the same line, when she was the greyhound of the Atlantic. The stewards are berthed amidships, the seamen and firemen forward. Most of the stewards live in large dormitories with double-tiered iron beds all round, while the seniors have one, two, or three berthed cabins. The seamen and firemen have small cabins each holding three or four men; and what different places they are from the old fore-castle! I estimated one of these cabins, for two men, as 9 ft. high, 9 ft. long, and 8 ft. wide, 728 cub. ft., giving each man, not the 120 cub. ft. required by the law, but 300 cub. ft. of air space, and there was besides an air trunk and a 10-in. side port. 120 ft., be it remembered, is all that the Merchant Shipping Act requires. The rest is supererogation. There was in this cabin an exposed iron beam; that it had no insulating cork-paint made me anxious, but I was assured that the ship was kept so warm by steam-radiators that even a naked iron beam like this did not sweat. There was a little cabin, also a mess place, for the four boys who do duty on the bridge, and if only boys could go on always serving in the *Aquitania* there would be little hardship in a seafaring life beyond the weather. There are large mess decks for the seamen and firemen, well warmed and well lighted, with tables for their food and benches to sit on. Not least of the benefits is it that the men do not have to prepare their dinners, nor do they get them cooked by an inferior cook, for all their food is drawn from the ship's galley where the large staff of cooks prepares food daily for some 4000 people. Compare all this with accounts of the merchant seaman's lot even 10 years ago!

Stewards and their Meals.

But I saw no mess places for the stewards. In the *Campania* 15 years ago many of the stewards and stewardesses sat down to meals in the saloon after the passengers had finished, and it was a pleasure to see them comfortable. Consequently, I was disappointed to find that in the *Aquitania* the company have gone back to the evil custom of giving the stewards good food, indeed, but no table at which to eat it. It always pains me when I am travelling by sea to observe the stewards standing up to their meals at the pantry counters; not only the position but the oppressive heat must tend to wear them out and prevent the companies from getting their best service. I am sure that with a little consideration the company can better this hardship, which is far from inevitable.

The *Aquitania* no longer burns coal, only oil. That also makes for the comfort of the crew. I noticed there seemed few baths for firemen, and asking a fireman who was by if there were others, he told me baths were less necessary now, the work was so clean; indeed, it was unnecessary to change your clothes at the end of a watch in an oil-fired stokehold. Oil has enormously improved the comfort and status of the

fireman. By lessening his numbers it has made room in the ship for allotting greater space to the crew individually, and for increasing their comfort, as I have said.

My thanks are due to the company, and to the various officers of the ship, who, themselves very busy, yet made a little time to show me everything, and to answer courteously all my many questions.

UNEMPLOYMENT INSURANCE IN RELATION TO NATIONAL HEALTH.

THE Unemployment Insurance Act, 1920, has received the Royal assent, and will come into operation on Nov. 8th. Public attention has been so much occupied with foreign politics and with domestic problems of more immediate interest, or making more insistent claims for consideration, that the passage of a measure affecting a vast number of employers and employed persons will perhaps only be realised by many of these when they find themselves called on to pay their contributions under it. Many such will have forgotten that the National Insurance Act, 1911, not only introduced a compulsory system of health insurance, but also provided, more or less experimentally, for compulsory insurance against the ill-effects of unemployment in certain scheduled trades. Presumably the experiment has been found to be successful, for the new Act extends compulsory insurance to substantially all persons for whom health insurance contributions have now to be paid.

Persons Exempted from the Act.—Employers' Contributions.

Outworkers, agricultural workers, and persons in private domestic service are exempted from its operation, as are also certain classes of employed persons whose rights and conditions of employment render such insurance unnecessary in their case. These, however, are for the most part persons excepted from the operation of the Health Insurance Acts. Under the Unemployment Insurance Act workers over 70 years of age will be insurable, except in the case of old-age pensioners, who are excluded both as regards contributions and benefits. Even with the exceptions enumerated above it is estimated that about 8,000,000 persons will for the first time become insured against unemployment, making up the total of those so provided for to 12,000,000. Clerks and other non-manual workers will note that they are included if their remuneration does not exceed in value £250 per annum.

The contributions of employers will range from 4d. per week for men over 18 years of age to 2d. for girls between 16 and 18, and the employee will contribute from 4d. to 1½d. according to age and sex, payment being made by special stamps in the manner with which health insurance has made all familiar. Benefits will be 15s. per week for men, 12s. per week for women, and half the full rate for contributors under 18 years of age. The Act provides further for certain returns of contributions at the age of 60, and for the substitution of special schemes giving equal or superior advantages with the approval of the Minister of Labour.

Interdependence of Health and Unemployment Insurance.

Outwardly the connexion between health insurance and unemployment insurance is not close, and when the original Act of 1911 was passed many objected to the inclusion of two subjects apparently disconnected and both of great national importance in one measure. Both health insurance and unemployment insurance, however, have as their object, or as one of the objects for which they have been brought into being, the provision of a means of existence for workers who from temporary, if disconnected, causes are unable to earn their living, and for those dependent upon them. If we consider the matter from this point of view we see at once that there is a hardship affecting an unemployed worker when he finds himself deprived of the means of buying bread for his children

through no fault of his own, and when he sees a neighbour equally with himself deprived of wages, equally with himself not responsible for his plight, saved by a provision of the Legislature, at any rate, from the urgent pressure of hunger. There is also the more important consideration of the inexpediency, from a national point of view, of allowing the worker, his wife, and his children to deteriorate physically during those periods of enforced idleness which appear to be inseparable from industrial employment. The maintenance of the nation's health is one of the first, if not the first, duty of those who govern it, and is a duty receiving year by year a fuller measure of recognition. Under the Insurance Acts it will be the joint care of the recently constituted Ministry of Health and Ministry of Labour, the latter contributing its share by attending to the case of the wage-earner who is incapacitated as such though enjoying his full bodily health.

Sir John Simon's View.

Sir John Simon, then Solicitor-General, in an introduction contributed by him to Mr. Orme Clark's treatise on National Insurance, called attention to this interdependence of health and unemployment insurance, though not quite in the above sense, describing the inclusion of the two in a single Act of Parliament as due to an overwhelming reason of practical convenience. He pointed out that it was a necessary condition for receiving unemployment benefit that the unemployed person should be "capable of work," and that the condition for receiving sickness benefit was that the candidate for it should be "incapable of work." He evidently regarded it as likely that if one form of insurance came into being before the other there would be a temptation to make unjustified claims upon the fund first set up. It had been at one time proposed to make unemployment insurance antecedent to health insurance, but to have done this, Sir John Simon apprehended, would have made the man who lost work through ill-health find it to his advantage to declare himself sound, which is obviously undesirable. The two halves of the new scheme of insurance, he therefore submitted, ought to work side by side, the sharp distinction referred to between the conditions to which the different benefits attach being carefully drawn and maintained.

Practical Importance of the Combined Measures.

Looking back thus on the words written by a law officer of the Crown nine years ago we can safely infer that so far as the Government of that day was concerned the association of unemployment insurance with health insurance was designed and was recognised as of practical importance, and also that the extension of the former has only been delayed by the war. Having regard also to the fact that the present Prime Minister was mainly responsible for the introduction of national insurance in 1911, we look upon the Unemployment Insurance Act of 1920 as evidence of his satisfaction with the result of national insurance carried out upon the administrative lines which he laid down. The experiment of unemployment insurance has now been made on a comparatively small scale in the building, shipbuilding, and a few other trades. Experience on a far larger scale has been gained in health insurance, for the value set upon which in the public estimation the medical profession may regard itself as mainly responsible. Without public appreciation of the success of health insurance viewed as a whole it would hardly have been possible for any government to introduce another widespread measure of insurance, dependent for its funds upon a system of weekly contributions. We cannot forget that that system was at first chidden almost universally as irksome, unnecessary, and wasteful of time, but it now appears to be accepted as part of the nation's life on account of the results achieved. We look forward to similar acquiescence in the exactions, as at first they may be considered, of unemployment insurance, and to results in the maintenance of the public health, supplementary to and not less important than the results to be achieved by it in modifying and allaying social unrest.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Local Authorities and the Public Health.

THE deadlock which has arisen between many of the recently elected local authorities in Ireland and the Local Government Board is likely to cause serious interference with public health work. These authorities in which there is now a Republican majority—and they are very numerous—have, in the main, decided not to recognise the authority of the Local Government Board or to submit their minutes or books for the inspection of that body. The Government has replied by refusing to pay any grants to such recalcitrant bodies. Among the grants payable by the Treasury are half the cost of the tuberculosis service and three-fourths of the cost of the service for venereal diseases. It is likely that both these services will be seriously curtailed, if not completely stopped. It is understood that the Dublin Corporation has already decided to close its tuberculosis dispensary, hospital, and sanatorium, and it is probable that other authorities will have to follow its example. There are inconveniences in living in a country with two de facto governments, each ineffective, and neither recognising the other.

Abolition of Coroners' Inquests.

The *Dublin Gazette* last week contained a proclamation under the Restoration of Order in Ireland Act (1920), prohibiting the holding of coroners' inquests on dead bodies in ten counties of Ireland and in the county boroughs of Cork and Limerick. This step is said to be "for the purpose of securing the restoration and maintenance of order." Any inquests required to be held are to be held by a court of inquiry under the Army Act. It is to be regretted that the Lords Justices have considered it necessary to take this step. It is true that in many cases the coroners' courts, like the other courts of the King, have been unable to function. It has been impossible to find either jurors or witnesses. In this they are in the same case as the ordinary courts of assize. In some cases, too, juries have brought in verdicts which did not seem to be justified by the evidence. On the other hand, many juries have discharged their duties with courage and complete honesty, and their verdicts have a sanction in public opinion which a military court of inquiry cannot have. It must not be forgotten, too, that in many cases sudden death, calling for inquiry, has been due to military action, and the public is not likely in such cases to have much confidence in the impartiality of a military court.

Belfast Water-supply.

The Belfast Water Commissioners have decided to ask tenders for the construction of a great storage reservoir in the Silent Valley, a district high up amid the Mourne Mountains, and not far from the famous County Down golfing centre, Newcastle. Up to the present time they have had to depend on intermittent flows of water obtained from the Annalong and Kilkeel rivers in the Mourne range of mountains, supplemented by the enlargement of Lough Strannagh in the Kilkeel river catchment; but what is wanted for a big city like Belfast is a much larger and more regular daily flow of water all the year round to meet the growing demands for water by the citizens of Belfast and the inhabitants of the surrounding districts, and hence the immediate construction of a great storage reservoir right up in the Mourne Mountains, is what is now contemplated. This new reservoir, when completed, will have a storage capacity of 3000 million gallons and a tap-water area of over 250 acres, and it will by itself hold more water than all the existing reservoirs in the Woodburn and Stoneyford Belfast catchment areas at present in use. To many people the uselessness of constructing aqueducts from Belfast to the Mourne Mountains—a distance of over 20 miles—simply to tap a couple of rivers (the Annalong and Kilkeel) without any storage has been apparent, but now the making of a really large reservoir is to be begun.

Sept. 7th.

ROUMANIA.

(FROM OUR OWN CORRESPONDENT.)

Danger from Ice-creams.

AN important measure has been passed during 1920 dealing with ice-creams manufactured and offered for sale in Roumania. The ordinary method of making ice-cream as sold in the streets is to boil milk with or without the addition of some form of starch, together with a certain quantity of eggs, sugar, and flavouring. This mixture is allowed to cool naturally and afterwards is frozen. The cooling may take place under most unsavoury conditions, for instance, in a crowded living room, a disused (and unclean) outhouse, a confined and dirty back-yard, or even a scrap-heap; whilst, in addition, the surroundings among which the ingredients are mixed in some instances baffle description. Added to all this, the vendors and makers are generally Turks or Italians, whose ideas of cleanliness, whether personally or otherwise, differ materially from the here so much desired "western standard." Bearing these facts in mind it will readily be conceded that the ice-cream when sold may be contaminated in such a way as to be a danger to the consumer. To minimise this danger the board of hygiene have given orders for the control of the manufacture of ice-cream and other similar commodities. These must not be manufactured, sold, or stored in any cellar, shed, or room in which there is any inlet or opening to a drain, or which is used as a living- or sleeping-room. Special precautions must also be taken against infection or contamination of the ingredients used in the process of manufacture.

"Ptomaine" Poisoning from Meat.

A sharp outbreak of what would at one time have been labelled ptomaine poisoning occurring at Czernovitz in July has been carefully investigated, and the conclusions arrived at are of scientific interest. The outbreak, which affected 42 persons, of whom three died, was due to the *Bacillus enteritidis*, which gained entrance into pork sausages made on July 12th through the faecal pollution of the meat. The meat was left in the chopping-house in open vessels, and was contaminated from the large intestines of pigs which were brought into and cleansed in the chopping-house while the chopped meat was waiting for the next process in connexion with its conversion into pork pies. The practical lessons to be learnt from this outbreak are (1) the necessity for absolute cleanliness in all branches of sausage preparation so as to prevent the meat becoming infected; (2) the desirability of baking or cooking the sausage before use so as to raise it to a temperature sufficient to cause the death of any bacteria with which it is liable to be contaminated. In connexion with these preventive measures it is obvious that sanitary authorities should have powers to make and enforce regulations in regard to the preparation of pork sausages and pies, as well as that of many articles of food, thereby guaranteeing the constant supervision of all processes incidental to such trades. In the Czernovitz cases the symptoms were rapid onset, shivering, giddiness, headache, vomiting and diarrhoea, drowsiness, and extreme prostration. The incubation period varied from a few hours to a few days, and the patients either died or had a protracted convalescence; seven of them recovered only after six to eight weeks' illness.

Dust and Smoke Prevention.

The Bucharest City Council for Sanitation recently held a special meeting on the question of the dust and smoke nuisance. They emphasised the importance of dust collection and removal, and the need for municipal cleanliness in its widest sense. Roads should be made of hard and practically impermeable paving in thickly populated districts, instead of with defective stone and ordinary wood blocks; hoses should be used on all courts and alleys and small streets; and damp dusters should be used both in private houses and in public institutions. The problem of smoke and its preventives was also discussed.

Bucharest, August 15th.

Public Health.

ANNUAL REPORT FOR 1919 OF THE MEDICAL OFFICER OF HEALTH FOR NORWICH.

Dr. H. Cooper Pattin in his report gives the estimated population of the city as 124,997, and the area in statute acres 7923. The birth-rate for 1919 was 16·35 per 1000, which was below that of the 96 great towns (19 per 1000). The gross recorded death-rate was the same as the average of the 96 great towns—13·8 per 1000. The infantile mortality-rate among legitimate children was 78·4, and for the illegitimate 166·7 per 1000 births—a striking contrast. The zymotic death-rate was 0·32 per 1000. The comparative mortality figure was rather lower than that of the country as a whole—928 as against 1000. There was only one death from enteric, and the cause of the enteric fever cases does not appear to have been either overcrowding or bad drainage. However, in 84 per cent. of the affected houses the food of the family was stored in an unventilated receptacle in the actual living-room, and 84 per cent. of the affected dwellings were within 20 yards of a sewer grating or gully. 25 per cent. of the cases clearly recollected having consumed shell-fish prior to the attack. There were 140 notifications of phthisis and 79 of other forms of tubercle. 108 deaths were certified as due to pulmonary and 43 to other forms of tuberculosis, making a total of 151 deaths from tubercle, a figure much below the average of the last 25 years (221 deaths per annum). Dr. Pattin considers himself entitled to affirm that a diminution in the amount of tuberculous diseases is taking place. He says that he has long placed first in importance in the treatment of these diseases not houses, helpful as good houses are, but nutrition, and he confidently anticipates a further lessening of the amount of the disease among working people, proportionately with improvement in income, housing, and, above all, food. Other measures of great importance are the offer of gratuitous disinfection of all rooms in which a person has died from tuberculous disease, detailed instruction as to home treatment of affected persons, and the sorting out of tuberculous children. The Norwich City Council has appointed Dr. Theodore Fisher as tuberculosis officer, and only awaits the sanction of the Ministry of Health for the proposed site of their tuberculosis dispensary. It is also proposed to establish, in conjunction with the Norfolk County Council and the Borough of Yarmouth, a sanatorium and training farm at Stanninghall, near Norwich, where 700 acres, with farm buildings, and a farmhouse which makes quite a good administrative centre, have been procured and turned over to the joint committee by the Red Cross Society. A start has been made with a temporary pavilion accommodating eight males. An open-air school for children has also been inaugurated.

Housing conditions.—The total number of houses in the city is estimated to be nearly 30,000, and of these some 25,000 are occupied by the working classes. Compared with other large towns, the general character of the housing is fairly good, especially of the more modern dwellings, and there are many small gardens. Out of 5809 houses for the working classes inspected in 1919, 106 were overcrowded in respect of cubic space per head, and 458 had more than two persons per room. The health visitors paid 19,550 visits and revisits to houses, 5822 of them in connexion with medical inspection in the schools. They found in the dwellings visited 1801 sick persons. At their suggestion 95 houses and 238 persons were cleansed. The health visitors paid 2217 visits to the homes of the tuberculous, and found that 31·9 per cent. of affected persons had a separate bedroom, 14·1 per cent. had a separate bed in a double-bedded room, and no less than 54 per cent. shared a bed with another person. Dr. Pattin considers that about 4000 unfit houses will need to be replaced if a decent standard of comfort and accommodation is to be enforced. The council puts forward a scheme which has been approved by the Ministry of Health providing for the erection of 1200 new houses, and is making strenuous efforts to get these provided, but there are great difficulties owing to the cost and scarcity of trained labour and materials. It is hoped to procure the erection of 500 houses by the end of March, 1921.

School medical work.—11,674 children were inspected in the schools, and there were 453 re-examinations. 2498, including 589 cases of ringworm, were found to need treatment, and at the end of the year 2169 had received it. In some cases treatment was delayed by the advice of private doctors, and in others not undertaken; this was notably the case in dealing with adenoids and tonsils. At the dental clinic 4339 children were attended to. 1197 damaged permanent teeth were repaired with fillings, and 4165 teeth were extracted. One dental officer is not, however, considered sufficient to cope with the work amongst 19,000 children.

On the whole, Norwich may be considered a healthy city to dwell in, especially in comparison with other manufacturing towns.

"The chief occupations of such of its inhabitants as have to labour for their livelihood," says Dr. Pattin, "are boot-making, mustard and starch making, brewing beer, galvanising iron-wire, motor-engine and aeroplane construction; cocoa and aerated water production; banking; life, fire and accident insurance; teaching and preaching. The boot-making industry contributes a noticeable amount of phthisical cases, especially amongst the 'clickers'; I attribute this largely to the bad mechanical attitude imposed upon these workers—stooping with arms forward and chest cramped and retracted, and also to the apparent tendency of the less robust to drift into this branch of business."

The soil of the city is of a porous character, the higher levels being made up of glacial beds, through which the valleys have been excavated, exposing at their margins the crag formation and chalk, gravel, and alluvial deposits occupying the lower ground. The climate is relatively dry and bracing, and the rainfall low.

URBAN VITAL STATISTICS.

(Week ended Sept. 4th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 9·4, 9·9, and 9·9 in the three preceding weeks, rose to 10·0 per 1000. In London, with a population of nearly 4½ million persons, the annual death-rate was 9·7 per 1000, and coincided with that recorded in the previous week, while among the remaining towns the rates ranged from 4·2 in Gloucester, 4·8 in Gillingham and in Dudley, and 5·1 in Aberdare, to 15·4 in Ipswich and in Sunderland, 15·9 in South Shields, and 17·7 in Exeter. The principal epidemic diseases caused 255 deaths, which corresponded to an annual rate of 0·7 per 1000, and comprised 171 from infantile diarrhoea, 37 from diphtheria, 19 each from measles and whooping-cough, 8 from scarlet fever, and 1 from enteric fever. The deaths from infantile diarrhoea, which had increased from 87 to 150 in the four preceding weeks, further rose to 171, and included 34 in London, 20 in Hull, 10 in Liverpool, and 6 each in Sheffield and Sunderland. The mortality from the remaining diseases showed no marked excess in any of the large towns. There were 2402 cases of scarlet fever and 1404 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 2266 and 1391 at the end of the preceding week. The causes of 30 of the 3427 deaths in the 96 towns were uncertified, of which 7 were registered in Birmingham.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 12·3, 10·8, and 11·1 in the three preceding weeks, declined to 9·8 per 1000. The 206 deaths in Glasgow corresponded to an annual rate of 9·7 per 1000, and included 6 from infantile diarrhoea, 4 from whooping-cough, and 1 from diphtheria. The 55 deaths in Edinburgh were equal to an annual rate of 8·4 per 1000, and included a fatal case each of diphtheria and infantile diarrhoea.

Irish Towns.—The 109 deaths in Dublin corresponded to an annual rate of 13·7, or 1·6 per 1000 below that recorded in the previous week, and included 3 from infantile diarrhoea. The 97 deaths in Belfast were equal to an annual rate of 12·2 per 1000, and included 8 from infantile diarrhoea and 1 each from enteric fever and scarlet fever.

VITAL STATISTICS OF LONDON DURING AUGUST, 1920.

In the accompanying table will be found summarised statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious disease, it appears that the number of persons reported to be suffering from one or other of the ten diseases notified in the table was equal to an annual rate of 6·6 per 1000 of the population, estimated at

ANALYSIS OF SICKNESS AND MORTALITY STATISTICS IN LONDON DURING AUGUST, 1920.

* Including membranous croup.

4,358,309 persons; in the three preceding months the rates had been 6·3, 6·0, and 6·5 per 1000. Among the metropolitan boroughs the lowest rates from these diseases last month were recorded in Paddington, Chelsea, the City of Westminster, Hampstead, Holborn, the City of London, Lewisham, and Woolwich; and the highest in Fulham, Bethnal Green, Stepney, Poplar, and Bermondsey. The prevalence of scarlet fever was somewhat greater than in the preceding month; this disease was proportionally most prevalent in Fulham, Bethnal Green, Stepney, Poplar, and Bermondsey. The Metropolitan Asylums Hospitals contained 2251 scarlet fever patients at the end of the month, against 1671, 1674, and 1940 at the end of the three preceding months; the weekly admissions averaged 335, against 228, 251, and 284 in the three preceding months. Diphtheria was slightly less prevalent than in the preceding month; the greatest prevalence of this disease was recorded in Hammersmith, St. Pancras, Islington, Stoke Newington, Bethnal Green, and Poplar. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 1783, 1590, and 1470 at the end of the three preceding months, further fell to 1388 at the end of August; the weekly admissions averaged 173, against 214, 189, and 179 in the three preceding months. The prevalence of enteric fever was about half that in the preceding month; of the 22 cases notified during the four weeks ended August 28th, 3 belonged to St. Marylebone, 3 to Wandsworth, and 2 each to the City of Westminster, Islington, Hackney, Poplar, and Greenwich. There were 17 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 18, 19, and 24 at the end of the three preceding months; the weekly admissions averaged 3, against 3, 3, and 6 in the three preceding months. Erysipelas was proportionally most prevalent in Hampstead, the City of London, Bethnal Green, Stepney, Southwark, and Woolwich. The 31 cases of puerperal fever notified during the month included 4 in Stepney, 3 in Kensington, and 3 in Wandsworth. The 10 cases of cerebro-spinal meningitis included 3 in Islington; while the 5 cases of poliomyelitis belonged respectively to Hammersmith, Islington, Shoreditch, Bethnal Green, and Lambeth.

The mortality statistics in the table relate to the deaths of civilians actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the four weeks ended August 28th the deaths of 3101 London residents were registered, equal to an annual rate of 9·3 per 1000; in the three preceding months the rates had been 12·4, 10·3, and 9·6 per 1000. The death-rates ranged from 6·3 in Paddington, 6·4 in Hampstead, 6·8 in the City of Westminster, 7·0 in Hackney, and 7·3 in Hammersmith, to 11·4 in Kensington, 12·0 in Stoke Newington, 12·0 in Poplar, 12·6 in Holborn, 13·7 in Shoreditch, and 14·1 in the City of London. The 3101 deaths from all causes included 193 which were referred to the principal infectious diseases; of these, 6 resulted from measles, 8 from scarlet fever, 56 from diphtheria, 15 from whooping-cough, 3 from enteric fever, and 105 from diarrhoea and enteritis among children under 2 years of age. No death from any of these diseases was recorded last month in the City of London. Among the metropolitan boroughs the lowest death-rates from these diseases were recorded in Paddington, Chelsea, the City of Westminster, St. Marylebone, Hampstead, St. Pancras, and Greenwich; and the highest in Kensington, Shoreditch, Bethnal Green, Stepney, Poplar, and Lambeth. The 6 deaths from measles were 44 below the average number in the corresponding period of the five preceding years. The 5 fatal cases of scarlet fever were 1 more than the average; of these 2 belonged to Kensington and 2 to Bethnal Green. The 56 deaths from diphtheria exceeded the average by 20; the greatest proportional mortality from this disease occurred in Hammersmith, Islington, Stoke Newington, Bethnal Green, Poplar, and Lambeth. The 15 fatal cases of whooping-cough were 14 fewer than the average; of these, 3 belonged to Hackney, 3 to Poplar, and 2 to Wandsworth. Three deaths from enteric fever were registered during the month, against an average of 6. The 105 fatal cases of infantile diarrhoea were 64 below the average; the greatest proportional mortality from this disease occurred in Holborn, Finsbury, Shoreditch, Stepney, Poplar, and Battersea. In conclusion, it may be stated that the aggregate mortality in London during August from these principal infectious diseases was 35 per cent. below the average in the corresponding period of the five preceding years.

"Audi alteram partem."

DR. MARCEL BLOCH ON COAGULATION.

To the Editor of THE LANCET.

SIR.—In the French Supplement to THE LANCET of August 7th a paper appeared by Dr. Marcel Bloch on the coagulation of the blood, and you have already commented on the surgical interest of his work in your issue of August 21st. Dr. Bloch puts forward his views as to the part played by calcium in the blood in the phenomenon of coagulation, and advocates a method of measuring the coagulability of the blood, which I may for clearness resume very briefly. His method is based upon dilution and inactivation of the calcium in the blood by means of a solution of sodium citrate. To various tubes containing equal quantities of citrated blood increasing amounts of a solution of calcium chloride are added, and the tubes showing commencement and end of coagulation noted. By means of this method pathological variations of coagulability have been determined. As a result of these observations Dr. Bloch has formulated a theory of the coagulation of blood, the prime factor in the process being calcium salts. It is well known that calcium is essential for the clotting of blood, but it appears from Dr. Bloch's paper that too much importance is given to the part played by calcium salts without any real evidence to support this claim.

It may fairly be assumed, in the present state of our knowledge, that some of the calcium is combined with the proteins in the blood, but I can find no evidence to support the view that it is all in this form. Further, there is no real evidence of the way in which sodium citrate prevents coagulation, and certainly less of the actual dose required to prevent coagulation. In an investigation of the calcium metabolism in certain bone diseases it has been frequently observed that the blood coagulates very rapidly, even when three times the usual amount of sodium citrate is added. Again, it is a noteworthy feature that the blood in alcoholism clots very readily; and here, again, sodium citrate is unable to prevent it. This increased coagulability of the blood is naturally beneficial in such cases, but certainly deserves attention when the donor in a blood transfusion has partaken of alcohol previously—a not uncommon occurrence if opportunities are provided. It is in just such cases that sodium citrate probably assists rather than retards coagulation, a fact which may further explain its observed toxicity. That the results produced were in any way due to impurities in the sodium citrate was negated by the use of absolutely pure sodium citrate.

The same effects have been observed, when potassium oxalate is substituted for sodium citrate. Thus in certain cases coagulation occurs whether the calcium salts have been non-ionised by citrate or precipitated by oxalate. The effects of alcohol on the complement-deviation test are familiar, and in this case we know that the action is a purely physical one, and it is suggested that the same change occurs in the blood of alcoholics, or in persons who have consumed alcohol just previous to the test. The physico-chemical basis of coagulation has much to recommend it since we are dealing with a colloidal solution and associated electrolytes, such as calcium. The activation of the electrolytes is by no means as simple a process as we are led to believe, but it would appear that changes in the reaction of the blood may play a not inconsiderable part. The changes may possibly be of small dimensions, hence the necessity of using the most delicate physico-chemical methods for their detection. This is the present objective.

The very interesting hypothesis put forward by Dr. Bloch may be true, but I for one require further proof before accepting it as the only explanation of this relation of calcium to coagulation. There is still a considerable

amount of confusion due to the invention of a number of different names to various constituents taking part in the process of coagulation. It has the merit of simplicity, but all the recorded facts unfortunately do not fit in with such a view. It does not explain why certain blood samples coagulate even in excess of sodium citrate or potassium oxalate. Further, with experience of removal of blood for various analyses, it is well known that if too much citrate or oxalate is present the action of chemical coagulants is retarded and often incomplete. The action of non-ionised or inactivated calcium in such a medium is almost negligible, and leads one to suppose that the sodium citrate has a further action so far unexplained. The coagulation of the blood is of such importance as to warrant close attention, and further evidence along the lines already pursued by Dr. Bloch and others will be looked for eagerly.—I am, Sir, yours faithfully,

Sept. 6th, 1920.

R. L. MACKENZIE WALLIS.

SMOKING AND OUTPUT: A SUGGESTION.

To the Editor of THE LANCET.

SIR,—In THE LANCET of July 17th you refer to the practice of permitting smoking in workshops, which seems to be gaining favour with employers. It is now stated that the practicability of permitting smoking in certain Royal dockyards is being considered by the Admiralty. Several manufacturing firms in Lancashire, especially in the Manchester area, have allowed their workmen to smoke during a certain period every day. After an experiment extending over several months the Vickers Metropolitan Co. have found that the permission to smoke for a short period daily under regulated conditions has increased the output, secured a more contented spirit among the men, and in general improved the efficiency of the workshops. Under conditions of strict prohibition it was found that the desire to smoke became so keen and overpowering that loitering in search of an opportunity for a surreptitious smoke was a common practice.

Another symptom of the clamour for official recognition of "smoking time" is the demand of students of the London County Council for permission to smoke at its evening classes. It is recorded that during the Great Plague in 1665 all the Eton boys were obliged to smoke in school every morning. During the war it was found that fatigue parties worked all the better, as did troops in training, when allowed a short time to rest and smoke. The effects on efficiency of a regulated well-timed smoking pause might well receive the attention of the Industrial Fatigue Research Board. If elusive entities of unknown chemical constitution, such as so-called vitamins or nutrines can exercise powerful effects on the human organism, there is much to be said for a thoroughly scientific investigation of the influence on the workers' daily "output" of the products of a drug of which at least some of the chemical constituents are known. A custom and solace, originally barbaric in origin, which has invaded all civilised countries and communities and is now practised by both sexes of humanity at practically all ages, must have some deep and far-reaching physiological and psychological significance.

I am, Sir, yours faithfully,

Manchester, August 30th, 1920.

WM. STIRLING.

MIKULICZ'S DISEASE.

To the Editor of THE LANCET.

SIR,—The case of Mikulicz's disease reported by Dr. S. G. Askey in your issue of Sept. 4th reminds me that during the last four or five years I have seen three cases of the disease, all in white people, so that it is perhaps not so uncommon as might be supposed.

One case was that of a Greek lady about 60 years of age, whom I saw, in consultation with Dr. Alice Vance Knox of Highgate, some two or three years ago. There was a moderate painless enlargement of both parotids, and also of the submaxillary glands. Moreover, the parotids seemed at times to manifest some acute or subacute inflammatory

change, and when I saw the patient it was possible to squeeze a drop or two of thick clear mucus into the mouth from the unduly prominent orifice of Stenson's duct. But the symptom which was giving rise to most discomfort was the suppression of saliva. This, which, by the way, is not an invariable feature of the disease, was in her case absolute. Neither at meals nor at any other time was the patient's mouth even moistened with saliva, and the tongue, the lips, and the buccal surfaces of the cheeks were parched. As may readily be imagined, the discomfort resulting from the drying up of the secretion was very great. Salivary stimulants like sweets and acids only induced an aching or drawing sensation in the glands, and the patient had to be continually sipping water. In addition to the dryness of the mouth the conjunctivæ also were dry, for there was a complete absence of tears, so that when she had occasion to weep that act had to be effected without the usual overflow from the eyes.

A second case is one which I saw a few months ago in a middle-aged Scotsman. Fortunately for him the secretions had not dried up, but the parotid glands were both enlarged, and for several years he had been subject in an even more pronounced form than the first patient to periodical attacks of inflammation in the enlarged glands, lasting for about ten days and then gradually subsiding. When I saw him he had just reached the end of one of these exacerbations and muco-pus could be expressed from the duct. X ray examination of the glands and ducts, by Dr. Robert Knox, failed to reveal any calculus. From the gland secretion his own medical man, Dr. G. MacLellan Blair, of St. John's Wood, N.W., has had a vaccine made, and he reports that the patient is very much the better for it. Potass. iodid. is also being given.

The true nature of Mikulicz's disease is at present uncertain. The suggestion has been made that the enlargement of the glands may arise from a variety of causes. But while this may be admitted, nevertheless the participation of the lacrymal glands surely indicates that there must be some specific blood infection responsible for the changes. I am not aware whether the condition of the pancreas has been investigated. The disease is extremely chronic, and except for the objection felt by the patient to the fullness which the swellings impart to the face, and apart from such distressing symptoms as may be induced by the suppression of gland secretion, it does not seem to give rise to any serious phenomena.

I am, Sir, yours faithfully,
DAN MCKENZIE.

London, W., Sept. 4th, 1920.

PS.—Since the above was written I have seen what looks like a fourth case of the same disease.

LEPROSY IN THE PHILIPPINES: A CORRECTION.

To the Editor of THE LANCET.

SIR,—In the annotation on Leprosy in India in THE LANCET of May 1st you record the impression given at the February Leper Conference in Calcutta that the segregation of lepers in the Philippine Islands has given as wonderful results as were claimed for Sweden, Germany, Norway, and Iceland. But you will note from the following table of our Philippine Health Service, certified by the acting director, that the annual admissions in our leper colony for the last 14 years and 5 months have fluctuated within relatively narrow limits and afford no sufficient evidence that segregation has solved our problem.

Lepers Admitted and Remaining in Culion Leper Colony,
1906 to 1920.

Year.	Admitted.	Remaining.	Year.	Admitted.	Remaining.
1906 (July-Dec.)	802	546	1914	859	3602
1907	690	780	1915	555	3680
1908	1603	1126	1916	966	4265
1909	1378	1726	1917	613	4485
1910	930	2172	1918	973	4692
1911	889	2511	1919	551	4706
1912	964	2991	1920 (Jan-May)	225	4736
1913	795	3298			

I would like to invite your attention to a letter which I have recently addressed to Professor Milton J. Rosenau, of Harvard University, in connexion with a statement made in his book on "Preventive Medicine" regarding results of leper segregation in our islands. Rosenau admits that in the collections and segregations of lepers in Hawaii the results have been indifferent,

and that there must be considered some factor as yet unrecognised in the control and prevention of leprosy.

The erroneous impression that we are on the high road to a solution of our leper question might, if uncorrected, lead to neglect of further researches along other lines.

I am, Sir, yours faithfully,

JOSÉ ALBERT,

Professor of Pediatrics; Member, Council of Hygiene,
Philippine Health Service.

Manila, July 20th, 1920.

The letter from Professor Albert to Professor Rosenau contains the following passages:—

I have taken the liberty to call your attention to what appears to be a misstatement in the last two editions of your valuable and admirable book on "Preventive Medicine." I refer to that part of the Prevention of Leprosy Affecting these Islands (page 329) which reads: "In the Philippines segregation of all discoverable cases reduced new admission by 90 per cent."

I am enclosing a table given out by the Philippine Health Service, which sets forth all the yearly admissions in the Culion Leper Colony for the last 14 years and five months or since the institution of the drastic experiment of compulsory segregation. As may be seen from it, the rate of admission has never been reduced to anywhere near 90 per cent. at any one time. It is evident that in spite of the fact that many cases are hidden, yet the number of annual admissions has oscillated within relatively narrow limits, without any great noticeable decrease.

If we are to draw at all any conclusion from these figures, it would probably be in some way a conclusion similar to your statement for Hawaii that "segregation has so far had no effect upon the prevalence of the disease, and that there are factors in the control of leprosy not yet understood."

THE FRACTIONAL TEST-MEAL.

To the Editor of THE LANCET.

SIR,—The article by Dr. J. A. Ryle on the fractional test-meal in your issue of Sept. 4th raises afresh the question of the value of test-meals. Concerning the one-hour test-meal Dr. T. R. Brown, physician in charge of the gastro-intestinal clinic of the Johns Hopkins Hospital, wrote in 1916:—

"It was not many years ago that the absence of hydrochloric acid in the gastric juice was considered, if not diagnostic, at least extremely suggestive, of gastric carcinoma. To realise the error in this point of view, and to show that in the vast majority of cases achylia is associated with benign conditions, one has but to mention its presence in a large series of cases."

The writer then proceeds to enumerate 13 groups in which achylia occurs. Not only is gastric carcinoma but one among many of the causes of this condition, but when this particular disease happens to be responsible for the achylia, the one-hour test-meal is of little value, for when hydrochloric acid is absent, the growth is inoperable.

Accordingly, while great advances were being made in the Röntgen diagnosis of diseases of the alimentary canal, the one-hour test-meal lost ground, because it failed to provide information leading to practical results at all commensurate with the difficulties of popularising among patients the old-fashioned stomach-tube. In institutions it hardly held its own with the X rays as a test of gastric motility. For example, in the Mayo Clinic in 1914 a series of 950 patients were examined both by X rays and the single test-meal and the results checked by subsequent operation. The X rays were found to provide the more sensitive test. It was in these circumstances that the view gained ground that the study of the gastric, pancreatic, and intestinal secretions added little, if anything, to the resources of the clinical worker.

We have therefore to inquire at the outset whether the fractional test-meal supplies something which the older method lacked that may win for it a permanent place in the laboratory. Now no stomach containing bismuth, barium, or a tube of any kind whatever is working under physiological conditions, but with Einhorn's tube this fallacy almost disappears, for the inconvenience to the patient is practically negligible. The fractional test-meal provides, then, a picture of the secretory function of the stomach and duodenum obtained under conditions which fairly approximate to the normal. Quite apart from questions of motility, if these secretory studies furnish data of value either in diagnosis or in treatment the case for this method is established. My estimation of the value of such observations of the secretory function throughout digestion and in the resting period is based upon a study of the

American literature, where since 1914 a great body of evidence has accumulated, and upon my experience of fractional test-meals during the past six months at St. Mary's Hospital.

The position is very fairly stated by Rehfuß and Hawk.¹ No extravagant claims are advanced; the method is a useful, if modest, addition to our means of investigation, and we surely have need of every measure that can in any way contribute to accuracy in diagnosis. Moynihan writes:—

"More mistakes are made in the diagnosis of gastric ulcer than in the case in any other abdominal disorder. If all the methods of examination are strictly brought to bear upon cases commonly referred to as those of gastric ulcer, it will be found that in the majority the diagnosis cannot be upheld."

This, apparently, is also the experience of the Mayo Clinic, for Smithies, in an article printed in June this year, states that only 53 per cent. of patients sent to hospital diagnosed as gastric ulcer turn out to be such.

The time, then, is not perhaps inopportune for advancing a plea that no stone should be left unturned in the quest for greater accuracy in gastro-intestinal diagnosis. The first fine careless rapture of our surgical brethren, inspired by the early and brilliant results of gastro-enterostomy, has passed. A more sober spirit is abroad. Many cases have been successfully relieved, others have now been followed from the time they leave the surgeon's hands, through a period of apparent cure, to the return, and often aggravation, of the old symptoms. There has arisen a feeling that more careful selection of cases for operation, based upon exhaustive investigations, must precede further advances, and that any measures which contribute to our knowledge of either motor or secretory abnormalities, with its implied knowledge of the limits of the normal must tend to avert a repetition of these failures. Dr. Ryle's article is a step towards that end.

Nevertheless, it is as well to continue our search for answers to ultimate questions in gastric and intestinal pathology along other lines. To quote the writer whose views open this letter:—

"An attempt to evolve a gastro-intestinal pathology fundamentally on the basis of secretory variations is to lean on a frail reed. The curve is only one of the many clinical data which does not furnish the answer itself, but which adds its little to the many other aids at our command in reaching a true conception of the underlying disease process."

I am, Sir, yours faithfully,

South Audley-street, W., Sept. 6th, 1920.

C. M. WILSON.

THE PROBLEM OF DENTAL DISEASE.

To the Editor of THE LANCET.

SIR,—I read with pleasure your annotation under this heading in THE LANCET of August 21st. In this connexion may be mentioned some clinical observations made by me at the Luxor hospital for natives in Upper Egypt prior to 1914. Neither appendicitis nor gastric ulcer appeared among my cases, and cancer was rare. Though syphilis was widespread, yet I found no cases of aneurysm or of locomotor ataxy. As regards cancer, the absence of post-mortem examinations may vitiate my impressions of cancer incidence, but I never saw any kind of growth in a breast nor any cases of mammary abscess. My friend Dr. G. W. Ellacombe, of Livingstone, Northern Rhodesia, had similar experiences among his native patients.

I suggest that immunity from appendicitis and gastric ulcer depended on the nature of the diet, as a result of which, I claim, the population had good teeth. May the absence of gastro-intestinal cancer be due to this also? I would suggest to the Rockefeller Institute that the study of the diet and diseases of the country Arab as compared with his brother living in Cairo and Alexandria might be of value. Owing to the spread of flour-mills and sweet-shops the diet is rapidly changing, but it is still possible to study the native eating coarse wholemeal unleavened bread, and no sugar beyond the natural solution which he extracts from the fibrous cane and from other fruits.

A short time ago Professor J. G. Adami was reported to have stated that the teeth of the U.S.A. citizen were far better than ours. With the utmost respect, I

¹ Journal of the American Medical Association, August 14th, 1920.

venture to doubt his statement. It is my belief that the teeth of American citizens are extensively diseased, and the very number and importance of their dental surgeons would seem to support my statement. Now that the U.S.A. have gone "dry," and in consequence still more "sweet," the dental surgeons and doctors will doubtless be busier than ever. The suggestion that 10,000 more dental surgeons are required in this country is also attributed to Professor Adami. I protest at being asked to pay for this expensive host of officials when the advanced disease which they are to scrape out and plug can be almost entirely prevented by common-sense feeding and discipline in the home. Dr. Sim Wallace and others have actually proved that prevention is simple and inexpensive. Dr. James Wheatley, medical officer of health for Shropshire, also has figures pointing to the improvement of the children's teeth under war circumstances which are arresting and which I trust he will publish. For example, cow's milk is an entirely unnatural food for the human child, and its consumption in large quantities may have disastrous results to the children and sick people whose staple diet it has become. Just as alcohol in the form of wine, beer, or spirits does no harm, but in many cases positive good when taken in moderation, so it is with commercial sugar and with milk. There is far too much stress laid to-day upon heat calories and far too little upon the number and kind of meals necessary to exercise the teeth and keep the mouth clean and healthy. Much money and illness and many operations for gastric ulcer and appendicitis could be saved by putting the true facts about dental caries before the women of the country.

I am, Sir, yours faithfully,

W. E. NICKOLLS DUNN, M.B. Lond.

Brighton, August 30th, 1920.

Medical News.

A JOINT Conference of the Central Association for the Care of the Mentally Defective and the National Special Schools Union will be held at the Church House, Westminster, from Thursday to Saturday, Nov. 25th-27th. The Right Hon. H. A. L. Fisher is expected to address the opening session, at which Mr. Leslie Scott will preside. Sir William Byrne will be in the chair on the second day, and Dr. A. E. Eichholz on Saturday morning. Further information from the honorary secretary of the Central Association, Queen Anne's Chambers, Tothill-street, London, S.W. 1.

UNIVERSITY OF LONDON.—Preliminary arrangements for advanced lectures in physiology for the session 1920-21, details of which will be announced later, show a varied programme of courses to be delivered by distinguished physiologists:—

During the first term at King's College Dr. C. Da Fano will lecture on Histology of the Nervous System on Wednesdays, at 4.30 P.M., beginning on Oct. 13th.

At the University Buildings, South Kensington, Prof. A. D. Waller (in conjunction with Mr. J. C. Waller) will give a course of eight lectures on Experimental Studies in Vegetable Physiology and Vegetable Electricity on Tuesdays, beginning on Oct. 12th.

During the second term Prof. M. S. Pembrey, at Guy's Hospital, will give eight lectures on the Physiology of the Embryo, Fetus, and Newly Born, on Thursdays, at 4.50, and Mr. J. A. Gardner will give a course on Bio-Chemistry (title and place not yet arranged).

In the third term a course of lectures by various lecturers, to be arranged by Prof. F. A. Bainbridge, at St. Bartholomew's Hospital, and Prof. H. E. Roaf will give eight lectures at the London Hospital on Reception of Sensory Stimuli.

All these courses are recognised as advanced lectures which a candidate for B.Sc. honours may name for part of his examination.

The following scheme of intercollegiate advanced work in physiology has been approved for the Honours B.Sc. Examination, and students of the participating colleges are free to attend all the courses:—

First term: Prof. W. M. Bayliss (University College), Physical Chemistry in Relation to Physiology.

Second term: Prof. W. D. Halliburton and Dr. Rosenheim (King's College), Advanced Chemical Physiology; and Prof. M. S. Pembrey (Guy's Hospital), Practical Work on Respiration.

Third term: Dr. J. S. Edkins (Bedford College), Advanced Practical Histology; and Prof. F. A. Bainbridge (St. Bartholomew's Hospital), course of practical work on Electrical Changes in Skeletal and Cardiac Muscle.

Students requiring further information regarding the lectures should address their inquiries to the heads of the laboratories at which they will be delivered.

MANCHESTER ROYAL INFIRMARY.—The course of post-graduate lectures held last year is to be resumed; the first lecture of this session will be held on Tuesday, Oct. 5th. Details of the course will be published in our Medical Diary.

POST-GRADUATE STUDY FOR GENERAL PRACTITIONERS AT ST. ANDREWS.—A short course of post-graduate study for general practitioners will be given at the Clinical Institute, St. Andrews, under the direction of Sir James Mackenzie, commencing on Monday, Oct. 11th. The course, to which only a limited number of members will be admitted, will consist of lecture demonstrations dealing with the symptomatology of disease in its early stages, and will be supplemented by demonstrations on matters of clinical interest in anatomy, physiology, chemistry, bacteriology, ophthalmology, and radiology. The fee for the course is £10 10s. Graduates desirous of attending should communicate with the secretary, the Clinical Institute, St. Andrews, Fifeshire.

Professor J. Bretland Farmer, F.R.S., has been appointed a member of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research.

At the last meeting of the Dursley (Gloucestershire) Rural District Council the medical officer of health reported that six cases of enteric fever had been notified in a family at Uley.

THE West Suffolk Hospital at Bury St. Edmunds has decided to charge in-patients 10s. weekly. In addition to £6000 given by the Red Cross Society, £9000 will have to be raised locally for the reconstruction of the hospital.

THE sum of £2000 has been raised for the Bolingbroke Hospital, Wandsworth Common, by the Balham and Tooting Traders' Association.

BEQUEST OF A MEDICAL MAN TO HOSPITALS.—The late Mr. Edwin Allan Maling, consulting surgeon to the Sunderland Royal Infirmary, the Sunderland Eye Infirmary, and the Seaham Harbour Infirmary, who died on April 12th, left £500 to the Sunderland Royal Infirmary and £200 to the Sunderland and North Durham Eye Infirmary.

PRESENTATION TO A MEDICAL MAN.—At Penzance, on Sept. 1st, Dr. J. B. Page was presented by the local division of the St. John Ambulance Brigade with a silver cigarette box on the occasion of his leaving for New Zealand, as a mark of acknowledgment for his services as honorary instructor.

MEDICAL MAGISTRATES.—Dr. Sydney Garrett Vinter has been placed on the commission of the peace for the county of Cornwall. Dr. Arthur Briggs Dunne has been appointed a justice of the peace for the West Riding of Yorkshire. Dr. William Edmund Thomas has been placed on the commission of the peace for the county of Glamorgan.

St. Thomas's Hospital Old Students' dinner will take place at the Connaught Rooms, Great Queen-street, W.C., on Friday, Oct. 1st, at 7 o'clock for 7.30. The chair will be taken by Dr. Frederick Ford Caiger. Tickets, price 17s. 6d., can be obtained from the honorary secretaries at St. Thomas's Hospital.

At a recent meeting of the Axminster (Devon) Board of Guardians a letter was read from the Poor-law Medical Officers Association advocating the elimination of the appointment of part-time district medical officers and the appointment of whole-time medical officers; it was suggested that the board should have one full-time medical officer. The guardians did not consider it advisable to take any action in the matter.

DEVON V.A. HOSPITALS.—From 1914 to 1920 the number of patients admitted to the Devon V.A. Hospitals was 58,200. Of these, 45,475 were treated in V.A. hospitals and 12,725 in civil and private hospitals, as compared with 38,181 in Gloucestershire, 22,103 in Somerset, 21,100 in Dorset, and 6403 in Cornwall.

THE LATE DR. L. SHINGLETON-SMITH.—The death occurred recently of Lionel Shingleton-Smith, of Brecon, in his forty-fourth year, from injuries caused by a motor-car collision. The deceased was the second son of Dr. R. Shingleton-Smith, of Clifton, Bristol, was educated at Bristol and Cambridge, and qualified M.R.C.S., L.R.C.P. in 1905, and M.B., B.Ch. in 1908. After holding the posts of junior house surgeon and casualty officer at the Bristol Royal Infirmary, and house surgeon at the South Devon Hospital, he set up in practice in Brecon, where he was very popular. He held several union and other appointments, and was honorary physician to the Brecknock County and Borough Infirmary.

EXETER DISPENSARY.—At a special meeting of the governors of the Exeter Dispensary held on August 26th it was decided, owing to the increasing deficit on the working of the charity, to make a charge to patients for such things as medicines and dressings.

ROYAL DEVON AND EXETER HOSPITAL.—A special meeting of the governors of this institution was held on August 26th, when it was decided to alter the rules so as to provide for a charge being made for in- and out-patients. It was also determined to alter the recent decision of the governors, and to use the second storey of the "Victory Wing" for the accommodation of nurses instead of for a children's ward. The children will be provided for by erecting a corridor or bungalow wing in the garden of the hospital. The adoption of this plan, towards which an anonymous donor has already given £500, will result in a saving of £5000.—Dr. J. Delpratt Harris has been appointed honorary consulting medical officer to this hospital. Dr. Harris has been connected with the institution since 1881, when he inaugurated the electrical department, which has now been brought up to modern requirements.

THE LATE DR. R. P. MITCHELL.—Dr. R. P. Mitchell, who died recently in East Africa, had the distinction of serving with the South African Medical Corps on military service in East Africa for three years. Most of his professional career was spent in the Transvaal. He lived at Barberton from 1886 to 1894, when he went to the Rand, returning to Barberton 16 years later. Dr. Mitchell took a prominent part in the Jameson raid, and suffered imprisonment as a member of the famous Reform Committee.

BLIND PERSONS ACT.—This Act, which entitles blind persons to obtain, at the age of 50, a pension to which they would normally be eligible at the age of 70, comes into operation to-day. The Act is intended to apply to those who are so blind as to be unable to perform any work for which eyesight is essential. They must be natural-born British subjects who have resided in the United Kingdom since reaching the age of 30 for an aggregate period of not less than 12 years, and whose circumstances would render them eligible for old-age pensions if they were now 70 instead of 50 years of age. In the event of an appeal against the decision of the local pension committees as to whether a claimant fulfils the statutory condition of blindness, the Ministry may refer the case to a medical man for investigation.

THE LATE DR. G. BOWMAN.—In the death of Dr. George Bowman, whose funeral took place in Manchester on August 31st, the local community have sustained a distinct loss, even though he had given up active practice for some years on account of failing health. Born in 1843, George Bowman was the son of a practitioner of high repute in Old Trafford. He was educated at the School of Medicine in Manchester and at Edinburgh University, where he graduated M.D. in 1873, having qualified M.R.C.S. the previous year. He succeeded his father in practice, and was one of the quiet unobtrusive practitioners who are often, as in this case, among the most popular and successful in their districts. Dr. Bowman leaves a widow and two children.

The Services.

ROYAL NAVAL MEDICAL SERVICE: PAY OF RECRUITING OFFICERS.

By a revision of the salaries of officers engaged in recruiting for the Navy, notified in Admiralty Orders, medical officers engaged in the recruiting service receive £200 per annum, except the officer at Belfast, who will be paid £150 per annum.

TEMPORARY COMMISSIONS IN THE ROYAL ARMY MEDICAL CORPS.

In extension of the notice published in our columns on August 14th, the War Office is granting temporary commissions in the R.A.M.C. for a period of six months, for home service, to a limited number of medical men not over 55 years of age. Remuneration will be at the rate of £600 per annum for those who have not previously held commissions, and £650 for those who have served during the late war for a period of 12 months. In addition they will receive free rations or an allowance in lieu when rations are not issued in kind, and the regulated allowances and expenses when travelling on duty. An outfit allowance of £30 will be made to those to whom it has not been previously issued. Applications should be made at once in writing, to the Secretary of the War Office (A.M.D.1), London, S.W. 1, and should contain a statement of the candidate's age and previous service, if any.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Cmdr. J. C. F. D. Vaughan is placed on the Retired List.

ROYAL ARMY MEDICAL CORPS.

Temp. Major N. G. Cooper to relinquish the acting rank of Lieutenant-Colonel.

Major C. R. M. Morris to be acting Lieutenant-Colonel.

Capt. W. Foot relinquishes the acting rank of Major.

The undermentioned temporary Captains relinquish their commissions and retain the rank of Captain:—W. H. Harvey, W. E. Fraser, A. S. Cook, J. M. Wallace, H. Harrison, A. R. Berrie.

Temp. Capt. C. W. Joynt relinquishes his commission.

Capt. J. McP. Mackinnon is seconded for service with the Egyptian Army.

The undermentioned Lieutenants (temporary Captains) to be Captains:—G. E. L. Simons, E. Parker, L. G. Blackmore, V. J. Bonavia, D. J. Batterham.

SPECIAL RESERVE OF OFFICERS.

The undermentioned Captains relinquish their commissions on account of ill-health contracted on active service:—C. A. McGuire (granted the rank of Major) and G. E. Shand (retains the rank of Captain).

TERRITORIAL FORCE.

Lieut.-Col. A. T. Falwasser resigns his commission and retains the rank of Lieutenant-Colonel.

Major H. G. Smeeth (late Major, R.A.M.C., Spec. Res.), to be Lieutenant-Colonel and to command 1st East Lancs Field Ambulance.

Capt. C. H. Vernon (late Royal Air Force Medical Service) to be Captain.

Major (acting Lieutenant-Colonel) W. F. Roe relinquishes the acting rank of Lieutenant-Colonel on ceasing to be specially employed.

Capt. (acting Major) L. Beesley relinquishes the acting rank of Major on ceasing to be specially employed.

Cpts. W. W. Adamson and L. A. Williams resign their commissions and retain the rank of Captain.

Officers resigning their commissions and granted the rank of Major: Cpts. A. Anderson, C. S. P. Black, W. A. Brechin.

Capt. R. B. Lilly (late temporary Captain R.A.M.C.) to be Captain.

1st London General Hospital: Major L. B. Rawling is restored to the establishment.

3rd Northern General Hospital: Capt. G. S. Simpson is restored to the establishment on ceasing to hold a temporary commission in the R.A.M.C.

TERRITORIAL FORCE RESERVE.

Capt. C. T. Matthews resigns his commission and retains the rank of Captain.

ROYAL AIR FORCE.

Medical Branch.—The undermentioned are transferred to unemployed list: Capt. (acting Lieut.-Col.) A. P. Bowdler, Cpts. R. D. Jones and E. H. L. Le Clezio, and Lieut. R. I. Rhys.

Flying Officer G. H. H. Maxwell to be Flight Lieutenant.

INDIA AND THE INDIAN MEDICAL SERVICE.

Appointments.—Major L. Dunbar, R.A.M.C., to hold civil medical charge of Benares, vice Col. Walker, on leave. Capt. J. N. Turner, Agency Surgeon, Sibi. Capt. P. R. Vakin to hold civil medical charge of Roorkee, vice Capt. J. S. S. Martin. Capt. D. K. Sabhesan to hold civil medical charge of Roorkee, vice Capt. P. R. Vakin. Major P. C. Bedell, on return from military duty, to the charge of the Railway Dispensary, Moradabad. Capt. A. S. Fry, Medical Officer of Seistan Consulate. Major T. J. Carey Evans, Residency Surgeon, Mysore. Major H. H. Thorburn, Residency Surgeon, Baluchistan. Lieut. A. Innes Cox, to hold civil medical charge of the Allahabad District, vice Capt. L. A. P. Anderson. Major A. N. Dickson, to Peshawar. Major A. H. Proctor, First Resident Surgeon, Presidency Hospital, Calcutta.

Resignations.—Capt. P. S. Connellan has resigned his commission. Lieut.-Col. G. A. W. Hall retires from the Service. Major Norman White, Sanitary Commissioner to Government of India, retires, and has received an appointment with Ministry of Health, London. Lieut.-Col. Ashton Street, Principal of Grant Medical College, retires after 30 years' service.

Leave granted.—Lieut.-Col. H. J. Hugo, six months' leave. Lieut.-Col. J. W. Watson, eight months' leave. Major D. P. Gail, Civil Surgeon, Rajshahi, privileged leave for two months. Major W. D. Neal, Assistant to Superintendent, Medical College Hospital, Calcutta, six months' leave. Major V. B. G. Green-Armytage, Resident Surgeon, Presidency General Hospital, Calcutta, six months' leave. Major D. Heron, Medical Officer, Seistan Consulate, eight months' leave. Lieut.-Col. W. Young, Civil Surgeon, Lucknow, six months' leave. Lieut.-Col. L. G. Fischer, combined privilege leave and furlough. Major N. H. Scott, Civil Surgeon, Peshawar, combined leave. Major C. McDonald, Civil Surgeon, Sibsagar, four months' combined leave. Major S. Chuckerbutty, Civil Surgeon, extended leave for five months. Lieut.-Col. J. W. D. Megaw, Principal Medical College, Lucknow, six months' leave.

PAY OF ARMY NURSES.

An Army Order just issued announces the new rates of pay and retired pay of the Q.A.I.M.N.S. and of the permanent nursing establishment of the military families' hospitals, with effect from April 1st, 1920. Briefly the new annual rates of pay are as follows: Matron, £115, rising by £10 yearly to £185; assistant matron, £85, rising by £5 a year to £95; sister, £75, rising by £5 to £85; and staff or charge nurse, £60, rising by £2 10s. to £65. In addition, charge pay for matrons of Q.A.I.M.N.S. will be at rates not exceeding £45 a year, and for matrons of military families' hospitals £20 or £30 a year. Retired pay (with effect from April 1st, 1919) will comprise a service element (£3 for each year of service) and a rank element; but a nurse retiring with less than 10 years' service will not be eligible for retired pay. The maximum rates of these two elements together are as follows: Matron, £170; sister, £75; staff nurse or charge nurse, £55.

Medical Diary.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN, Hunter-street, Brunswick-square, W.C.

Post-Graduate Course on Venereal Diseases for Medical Women.

A Course arranged by the London (Royal Free Hospital) School of Medicine for Women, the Royal Free Hospital, the Elizabeth Garrett Anderson Hospital and the London Lock Hospital, for the instruction of qualified medical women in the Treatment of Venereal Diseases. The Course will extend over two weeks.

MONDAY, Sept. 13th.—12 noon, Lecture:—Mr. O. T. Dinick: Modern Treatment of Venereal Disease (at the London (Royal Free Hospital) School of Medicine for Women).

5 P.M., Mrs. Rorke, M.B.: Out-patient Cliniques for Women and Children (at the Royal Free Hospital, Gray's Inn-road).

TUESDAY.—9.30 A.M., Injections (at the London Lock Hospital, 283, Harrow-road, W.) 2 P.M., Mr. C. Gibbs: Lecture and Visit to Wards (at the London Lock Hospital, Harrow-road).

6.30 P.M., Dr. Ruth Balmer: Out-patient Cliniques for Women and Children (at the Elizabeth Garrett Anderson Hospital, 144, Euston-road, N.W.).

WEDNESDAY.—9 A.M., Dr. Morna Rawlins: Visit to Maternity Wards and Labour Department (at the London Lock Hospital, Harrow-road). 11 A.M., Dr. Mary Schofield: Pathological Demonstrations (at the Royal Free Hospital). 5.30 P.M., Mr. J. E. Lane: Lecture and Visit to Wards (at the London Lock Hospital, Harrow-road).

THURSDAY.—2 P.M., Mr. J. E. R. MacDonagh: Lecture and Visit to Wards (at the London Lock Hospital, Harrow-road). 5 P.M., Injections (at the Royal Free Hospital).

FRIDAY.—10 A.M., Mrs. Rorke, M.B.: Treatment Ante-natal Cases (at the Royal Free Hospital). 5 P.M., Mr. J. J. Abraham: Injections and Out-patient Clinique for Women and Children (at the London Lock Hospital, 91, Dean-street, W.). 6.30 P.M., Dr. Ruth Balmer: Out-patient Cliniques for Women and Children (at the Elizabeth Garrett Anderson Hospital).

SATURDAY.—9.15 A.M., Injections (at the Elizabeth Garrett Anderson Hospital).

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Sept. 13th.—2 P.M., Mr. B. Harman: Eye Department. 2.30 P.M., Dr. A. Saunders: Visit to Medical Wards.

TUESDAY.—2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. 2 P.M., Dr. Pernet: Skin Department.

WEDNESDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of Children. 2 P.M., Mr. D. Armour: Visit to Surgical Wards.

THURSDAY.—2 P.M., Dr. G. Stewart: Medical Out-patients. 2 P.M., Mr. B. Harman: Eye Department.

FRIDAY.—2 P.M., Dr. Burnford: Medical Out-patients. 2.30 P.M., Mr. Addison: Visit to Surgical Wards.

SATURDAY.—2 P.M., Dr. Owen: Medical Out-patients. 2 P.M., Mr. Sinclair: Surgical Out-patients.

Daily.—10 A.M., Ward Visits. 2 P.M., In-patient, Out-patient Clinics and Operations.

MALE LOCK HOSPITAL, Dean-street, W.

MONDAY, Sept. 13th, WEDNESDAY, AND FRIDAY.—5 P.M., Dr. C. Russ: Demonstration of the Treatment of Gonorrhoea by Electrolysis.

Communications, Letters, &c., to the Editor have been received from—

A.—Dr. A. Abrahams, Lond.; Capt. V. R. S. Ayer, I.M.S., Karachi; Prof. J. Albert, Manila.

B.—Prof. J. Barcroft, Cambridge; Dr. G. A. Brown, Glasgow; Dr. U. N. Brahmachari, Calcutta; Board of Scientific Societies, Lond.; Board of Control, Lond., Sec. of.

C.—Dr. W. Cramer, Lond.; Dr. H. P. Cholmeley, Forest Row; Central Association for the Care of the Mentally Defective, Lond.; Children's Country Holidays Fund, Lond.

D.—Dr. V. Dickinson, Lond.

E.—Mr. F. G. East, New Malden.

F.—Prof. J. E. S. Frazer, Lond.

G.—Lt.-Col. E. Goodall, Lond.; Capt. J. K. Gaunt, R.A.M.C.; Dr. W. H. Gregory, Beverley; Dr. L. H. Guest, Lond.

H.—Messrs. Handley Page, Ltd., Lond.; Prof. F. Hobday, Lond.; Mr. J. T. Henderson, Pietermaritzburg.

I.—India Office, Lond.

J.—Jamaica, Registrar-General of, Spanish Town.

K.—Dr. W. N. W. Kennedy, Croydon; Miss M. Knightley, Lond.

L.—Dr. E. B. Leech, Manchester; Dr. R. B. Low, Lond.; Dr. C. Lillingston, Gorleston; Dr. T. L. Llewellyn, Newcastle; Dr. J. R. Lord, Dalkey; Liverpool, Medical Officer of Health of.

M.—Dr. D. McKenzie, Lond.; Dr. J. J. R. Macleod, Paisley; Medical Research Council, Lond.; Dr. R. S. Miller, Lond.; Dr. A. A. Mumford, Manchester; Dr. W. C. Mackenzie, Lond.; Dr. G. N. Meachen, Westcliffe-on-Sea; Ministry of Health, Lond.; Metropolitan Asylums Board, Lond.; Ministry of Agriculture and Fisheries, Lond.; Ministry of Pensions, Lond.

N.—National Anaesthesia Research Society, Columbus, Ohio.

O.—Dr. T. Orr, Lond.

P.—Messrs. G. P. Putnam's Sons, Lond.

Q.—Queen's Hospital for Children, Lond., Sec. of.

R.—Dr. E. T. Roberts, Glasgow; Mr. A. M. Rovin, Detroit.

S.—Prof. W. Stirling, Manchester; Stretford, Medical Officer of Health of; Dr. R. E. Smith, Barry; St. Thomas's Hospital, Lond.; Society of Medical Officers of Health, Lond.; Dr. G. A. Stephens, Swansea; Mr. T. Sington, Manchester; Scientific and Industrial Research Dept., Lond.; Sir E. F. Schaffer, Cassis; Save the Children Fund, Lond.

T.—Dr. A. H. Thompson, Liskeard.

W.—Dr. A. Wood, Rugby; Dr. W. J. H. Wood, Southampton; Sir C. Wallace, Lond.; Capt. J. T. A. Walker, R.A.M.C. (T.F.); Dr. R. L. M. Wallis, Lond.; West London Hospital Post-Graduate College; Dr. K. M. Walker, Lond.; Dr. F. G. Wallace, Lond.; Dr. C. M. Wilson, Lond.; Dr. J. P. Walker, Ryde.

Appointments.

ALDOUS, G. F., F.R.C.S. Edin., has been appointed Consulting Surgeon to the Totnes Hospital, South Devon.
BURNELL, A. C., M.B., Honorary Assistant Surgeon to the Royal Cornwall Infirmary, Truro.
CRAIG, T. (Dudley), Medical Officer of Health to Weetslade Urban District Council.
GRANT, W., M.B., Ch.B. Edin., B.Hy., D.P.H. Durh., Medical Officer of Health to Easington Rural District Council.
GREGORY, W. H., M.D. Edin., Medical Officer to Poor-law Institution, Children's Home, Beverley and Tickton; also to Beverley Postal District.
STEVENS, B. C., M.D., M.S. Durh., F.R.C.S. Edin., L.R.C.P. Lond., D.P.H. Oxon., Assistant Medical Officer of Health and Chief Tuberculosis Officer, County Borough of Portsmouth.
THOMAS, R. E., M.D. Lond., B.S., M.R.C.S., L.R.C.P. Lond., D.P.H. Bristol, Assistant Medical Officer of Health, County Borough of Bath.

Vacancies.

East Africa.—M.O. to C.M.S. Kavirondo.
Eastbourne, Princess Alice Hospital.—Res. M.O. £175.
Glamorgan County Asylum, Bridgend.—Jun. Asst. M.O. £350.
Govan District Asylum, Cardonald, Glasgow.—Jun. Asst. P. £325.
Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—Asst. Anesth. £25. Also Asst. Res. M.O. £150.
Huddersfield Royal Infirmary.—Asst. H.S. £150.
Hull City Asylum, Witherby, near Hull.—Jun. Asst. M.O. £300.
Hull Royal Infirmary.—Asst. H.S. £150.
Ingham Infirmary and South Shields and Westoe Dispensary.—Jun. H.S. £175.
Lancaster County Asylum.—Asst. M.O. £300.
Lincoln County Hospital.—Jun. H.S. £150.
Liverpool, Brownlow Hill Poor Law Hospital.—Res. Asst. M.O. £300.
London Lock Hospital, Soho, W.—Hon. S.
Macclesfield General Infirmary.—Res. H.S. £200.
Maidstone, Kent County Mental Hospital.—Jun. Asst. M.O. £300.
Maidstone, West Kent General Hospital.—Two H.S.'s. £220.
Manchester, Ancoats Hospital.—Res. Surg. O. £250.
Manchester Royal Infirmary, Barnes Convalescent Hospital, Cheadle.—Res. M.O. £300.
Manchester Royal Infirmary, Central Branch, Roby-street.—Res. M.O. £250.
Margate, Princess Mary's Hospital for Children, Cliftonville.—Jun. Asst. M.O. £515 6s.
Metropolitan Asylums Board.—Jun. Asst. M.O.'s. £515 6s.
Metropolitan Hospital, Kingsland-road, E.—Cas. O. and Res. Anesth. £120. Also Asst. H.S. and Asst. H.P. £100 each.
Middlesex County Council, Harefield Sanatorium.—Res. Med. Supt. £700.
National Hospital for Diseases of the Heart, Westmoreland-street, W.—Out-patient M.O. £150.
National Hospital for the Paralysed and Epileptic, Queen-square, Bloomsbury, W.C.—Registrar. £200. Also Sen. H.P. £150.
Newcastle-upon-Tyne City Mental Hospital, Gosforth.—Sen. Asst. M.O. £500.
Newcastle-upon-Tyne, Royal Victoria Infirmary.—Hon. Asst. S.
Northampton General Hospital.—H.S. £200.
Nottingham City Education Committee.—Jun. Asst. Sch. M.O. £500.
Oldham Royal Infirmary.—H.S. £250.
Plaistow Fever Hospital.—Second Asst. M.O. £200.
Plymouth, South Devon and East Cornwall Hospital.—H.S. £200.
Preston and County of Lancaster Royal Infirmary.—H.S. and H.P. £180 each.
Prince of Wales's General Hospital, Tottenham, N.—H.P. and H.S. £200. Jun. H.S. and Jun. H.P. £120.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—H.S. £100.
Reading, Royal Berkshire Hospital.—H.P. and Second H.S. £200 each.
Royal Chest Hospital, City-road, E.C.—Asst. M.O. £450.
Royal Free Hospital, Gray's Inn-road, W.C.—Female Obstet. H.S. £50.
St. Mary's Hospital, Paddington, W.—Med. Supt. £350.
Salford Royal Hospital.—Res. Surg. O. £250. H.P., H.S., Jun. H.S., and Cas. H.S. £150 each.
Scarborough Hospital and Dispensary.—Two H.S.'s. £150.
Scottish Board of Health.—Dist. M.O.'s. £1000.
Sheffield Royal Hospital.—Asst. Cas. O. £150.
Sheffield Royal Infirmary.—H.P. and H.S. for Ear, Nose and Throat. £150 each.
Sheffield University, Department of Pathology and Bacteriology.—Director. £800. Asst. Director. £500. Curator of Path. Museum. £600.
Southampton County Borough.—Asst. M.O.H. £500.
South London Hospital for Women, South Side, Clapham Common, S.W.—Female Asst. S. Also Clin. Assts.
Surrey County Council, Urban District Council of Barnes.—M.O.H., &c. £800.
Sydney University, New South Wales, Australia.—Chair of Dentistry. £1100. Also Chair of Physiology. £1150.
Talgarth, Breconshire, South Wales Sanatorium.—Jun. Asst. Res. M.O. £400.
Uganda.—M.O. to C.M.S. Mengo Medical School.
Union Mental Hospital Service, South Africa.—Jun. Asst. P.'s. £400.
Ventnor, Isle of Wight, Royal National Hospital for Consumption and Diseases of the Chest.—Asst. Res. M.O. £300. Also Locum Tenens. 7 gs. per week.
Westminster Hospital, opposite Westminster Abbey.—Asst. H.S.
Westmorland Sanatorium and Home, Meathop, Grange-over-Sands.—Res. Asst. M.O. to the Westmorland Sanatorium and Asst. Tuberc. O. for Westmorland. £350.
Worcester County and City Mental Hospital, Powick.—Jun. Asst. M.O. £350.

Births, Marriages, and Deaths.

BIRTHS.

ADAMS.—On August 28th, at Prospect House, Clitheroe, the wife of Dr. F. S. Adams, of a son.
AUELING.—On Sept. 2nd, at Chalk Hill, Bushey, the wife of Kenneth Aueling, M.B., of a son.
BLOMFIELD.—On August 31st, at Cornwall-terrace, Regent's Park, the wife of Dr. J. Blomfield, O.B.E., of a son.
CONNAN.—On Sept. 1st, of 17d, Avonmore-road, W. Kensington, to Dorothy (Mackintosh), wife of Donald Murray Connan, M.B., B.S.—a daughter.
HEALD.—On Sept. 2nd, at Kington, near Welwyn, the wife of Lieutenant-Colonel C. B. Heald, C.B.E., M.D., of a daughter.
LITHGOW.—On August 30th, at The Close, Tetbury, the wife of Major E. G. R. Lithgow, R.A.M.C., M.R.C.S., L.R.C.P. Lond., of a son (Michael John).
MC CREERY.—On Sept. 2nd, at Huntly, Parkstone, Dorset, the wife of Major A. T. J. McCreery, M.C., M.B., B.Ch., B.A.O. Dub., R.A.M.C., of a daughter.
PAYNE.—On Sept. 4th, at Waungron-road, Llandaff, Cardiff, the wife of Dr. J. Rowland Payne, of a daughter.

MARRIAGES.

DEWAR—D'ALMAINE.—On Sept. 7th, at St. Nicholas Church, Abingdon-on-Thames, by the Rev. H. A. Kennedy, M.A., vicar, assisted by the Rev. R. C. MacKeown, M.A., Robert Scott Dewar, M.A., M.B., Ch.B., Glasgow, to Roubaix, elder daughter of Mr. H. G. W. d'Almaine, The Square, Abingdon.
HANCOCK—BRANWELL.—On Sept. 2nd, at Christ Church, Lancaster-gate, W., by the Rev. Geoffrey Browne, M.C., Allen Coulter Hancock, M.C. (with two bars), M.R.C.S. Eng., L.R.C.P. Lond., Major (late R.A.M.C.), to Vera Primrose Branwell, elder daughter of Mr. and Mrs. Alfred Branwell, Penzance, Cornwall.
REES—HUGHES.—On Sept. 2nd, at the Parish Church, Maidstone, by the Rev. Charles E. Hughes, vicar of Woodhouse, Sheffield, assisted by the Rev. Canon Hardcastle, vicar of the parish, William Arthur Rees, M.D., F.R.C.S., son of the late F. W. J. Rees, I.C.S., and Mrs. Rees, of Swanage, Dorset, to Olive Carey, second daughter of the late Henry A. Hughes, and Mrs. Hughes, of Maidstone, Kent.
SUTTON—GIBBS.—On August 28th, at St. Mary's, Bryanston-square, by the Rev. S. N. L. Ford, M.A., Captain W. H. Sutton, R.A.M.C., L.R.C.P., L.R.C.S. Ed., attached Egyptian Army, to Madeleine Ella, younger daughter of Mrs. W. H. Gibbs, Pinner-road, Harrow.

DEATHS.

ALBAN.—On Sept. 3rd, in London, after an operation, Evan Alban, M.D. St. And., M.R.C.S. Eng., L.S.A., of Aberayron, Cardiganshire, and formerly of Llandfeld, Sussex, aged 72 years.
EDWARDS.—On August 27th, at Tor-na-Dee, Aberdeen, Cyril Henry Edwards, M.B., B.S. Lond., M.R.C.S. Eng., L.R.C.P. Lond., L.D.S. R.C.S. Eng.
HARRIS.—On Sept. 1st, at Eastbourne, Frederick Rutherford Harris, J.P., of Llangibby Castle, Monmouthshire.
NOTT.—On August 26th, suddenly, from heart failure, while on a visit to the Engadine, Arthur Holbrook Nott, Lieutenant-Colonel, Indian Medical Service (retired), of 22, Drayton Court, London, S.W., second son of the late William Nott, of Devizes, aged 58.
PASLEY.—On August 26th, at Port Harcourt, Nigeria, Claud John Burgoyne Pasley, M.R.C.S. Eng., L.R.C.P. Lond., Colonial Medical Service, Captain, R.A.M.C.
N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

HEALTH TEACHING IN THE UNITED STATES: PROFESSOR SEDGWICK'S LECTURES AT CAMBRIDGE.

By SIR G. SIMS WOODHEAD, K.B.E., V.D., M.D., LL.D.,
PROFESSOR OF PATHOLOGY, UNIVERSITY OF CAMBRIDGE.

DURING the early part of the present Long Vacation Course the Cambridge medical students and others interested in the advancement of sanitary science and public health were privileged to hear something of the methods of sanitation employed, and of the health work now being carried on in the United States of America. After a recent visit to the United States a former vice-chancellor, Sir Arthur Shipley, arranged for Professor W. T. Sedgwick, of Boston, professor of biology and public health at the Massachusetts Institute of Technology, to visit Cambridge, attend lectures, and deliver a short course on the organisation of the United States Public Health and other sanitary services, and on the means adopted for education and training in these matters not only of public health officers and sanitary engineers but of the general public.

University and Technological Education in the United States.

In five lectures on this subject Professor Sedgwick set out clearly and concisely the important bearing of study and research on the organisation of public health services in America. Pointing out that England was the cradle of public health and sanitation, Professor Sedgwick stated that our local public health authorities had, in the first instance, assumed responsibilities that the State had failed—or had been unwilling—to shoulder, and that in America the development of sanitation had followed on much the same lines. In Germany, instead of beginning at the periphery of the system, they had attempted from a bureaucratic central organisation to build up and control a comprehensive public service and to lay down by line and rule the duties both of doctors and of the people. The central authority assumed powers and responsibilities that in Anglo-Saxon communities had early been acquired by local bodies. Only later had centralisation been adopted in the United States in order that general interests might be protected and common action taken in large areas, as, for example, in the matter of the protection of a river running through several States.

Dealing with impure water-supplies and their rôle in the production of typhoid and cholera, Professor Sedgwick emphasised the fact that organisms other than those producing cholera and typhoid sometimes accounted for more deaths than do water-borne typhoid germs, and referred to Mr. Allen Hazen's observation that for every death from typhoid resulting from infection through water two or three deaths occur from diseases such as paratyphoid, diarrhoea, and enteritis. Many cases of acute diarrhoea recover, others succumbing with alarming rapidity. In the United States the skilled layman appears to have played a much more important part in the advancement of preventive medicine and sanitation than he has been encouraged to play in this country. Sanitary engineering and public health problems are handled not only by laymen specially trained as health officers, but by medical men whose interest in what may be termed "bedside medicine" is comparatively slight. There has thus grown up a corps of sanitary officers of great value. One advantage of this system is that the clinician, whilst benefiting by the experience of the sanitary officer and utilising it to the full in his everyday work, need have no fear that the sanitary officer, who claims to be trained only in the preliminary science branches of medicine will feel called upon or competent to interfere in the diagnosis and treatment of the medical practitioner's private patients.

Laymen as Sanitary Officers.

The Massachusetts Institute of Technology, combining forces with the Medical School and the University of Harvard, was the first school in America to make any systematic attempt to train health officers, sanitary inspectors, and engineers. It was "an assembled school" in which a lecture on chemistry here, a lecture on physiology there, with a few special lectures added or thrown in, was deemed sufficient to serve the purpose. Later a more prolonged and complete course was provided. This was attended by medical men, of course, but also by graduates in science and engineering, who soon constituted a useful body of health officers for American towns. From this source have also been supplied sanitary workers in China, Fiji, and elsewhere,

members of a skeleton sanitary corps in the U.S. army and skilled men ready to undertake, under the American Red Cross, crusades against tuberculosis and other infective and parasitic diseases, not only at home but abroad, wherever the interests of America are involved or its sympathies aroused. Now, however, the good work has spread to the Johns Hopkins University, which up to 1918 had no adequate school of public health, but has since built up the most advanced and complete Public Health School in the United States. In 1914 the Rockefeller Foundation, realising the lack of trained personnel, and the fact that men who had passed through the ordinary medical curriculum were mostly neither qualified to deal with, or really interested in, public health, made arrangements to found at the Johns Hopkins University in Baltimore a well-equipped and fully endowed School of Hygiene, Preventive Medicine, and Sanitary Science which, though working with the medical department, should be separate from it. For the teaching at the Harvard Medical School and the Massachusetts Institute of Technology there was no endowment—nothing but the goodwill of certain professors and the students' fees—£50 a year from each of the few students. Now all this is being altered, and at Baltimore special departments are being planned, each to be placed under some distinguished teacher or organiser. Professor W. H. Welch, the well-known pathologist of the Johns Hopkins Medical School, has resigned that position to take up the duties of principal and director of this new school, and Dr. William H. Howell, professor of physiology and formerly dean of the Medical School, has accepted the post of assistant director. These appointments, were there nothing else, indicate the estimate formed by the highest educational circles of the new public health school. Up to June last only one student had graduated in public health from the Johns Hopkins School, but in Boston, with its enthusiastic personnel though smaller resources, some 50 candidates have already been trained in public health and sanitary science, and have graduated from the Harvard Technology School in these subjects. In both schools an attempt is being made to educate experts or leaders in sanitary investigation, organisation, and education. The schools are being fully equipped and staffed by a combination of the best organisers and teachers in the country. Professors of pathology, bacteriology, preventive medicine, biochemistry, physiology, engineering, hygiene, and the like are being appointed. Experts are dealing with biometrics and vital statistics; industrial hygiene; practical public health work and laboratory methods; social and mental hygiene; social service work in the people's homes and at the hospital; the nature and prevention of communicable diseases; parasitology and epidemiology; applied hygiene; immunology and serology; the principles of nutrition and the analysis of foods; sanitary engineering and allied subjects. Similar schools are to be founded and developed in San Francisco, New Orleans, and Chicago, and Professor Sedgwick points out that with such a nucleus as already exists there is no reason why a strong public health school of the same type should not be built up in Cambridge.

Propaganda Work.

One thing came out very clearly in Professor Sedgwick's lectures; our American brethren take a much more comprehensive view of the duties of sanitary and hygiene schools than do we in this country. In these schools they have developed a service for the education of the public, and lecturers and teachers are sent out trained to hand on to the public the elements of general and personal hygiene. For example, in connexion with the educational division of the American Commission for the Prevention of Tuberculosis in France, Professor S. M. Gunn (an American of Irish stock) has organised travelling exhibitions and "poster" services inculcating open windows, personal bathing and cleanliness, care of the teeth, and so forth. In their work in France the Commission had been content to popularise and organise knowledge already acquired, much of which was due to the efforts and research of French medical men and scientific investigators, which were second to none in the world. There was, however, in that country a lack of coördination and coöperation of public authorities and of public health education, and it was this education and coördination that the American Commission had attempted to bring about.

As an example of the kind of public health work that is now being initiated and carried on in the United States a Health Bulletin with the motto "The Health of the People the Beginning of Happiness," published by Dr. F. P. Denny, the health officer of Brookline, Massachusetts, a copy of which is sent out to every household in Brookline, was instanced. Professor Sedgwick explained that all manner of common-sense advice is given in this bulletin. The necessity of attention to small details is urged most strongly; the principle causes of death of Brookline residents are given and means of prevention suggested; the "wear and tear" diseases are described. The author advises that "a medical examination every year is the best kind of life assurance." He points out how some of the 65

deaths from pneumonia and influenza could have been prevented. Of cancer he asks: "Can it be cured?" "Tuberculosis," he says, "is preventable"; "Why, then, were there 25 deaths from this disease in Brookline?" "Flies are filthy"; "there are no substitutes for milk and the milk-supply should be the best obtainable"; a record, analyses, and reports on the milk sold in Brookline are given. Were we to publish similar records and reports in this country actions for libel might ensue. "Food hints" are given and specimen "low cost diets" for a family of five, with recipes, are included. Health maxims and aphorisms are quoted, and striking and easily remembered alliterative phrases given: "Flies, food, and fingers"; "Dirt, diarrhoea, and dinner"; "To cure is the cry of the past, to prevent is the need of the future"; "Health is easier kept than regained," and so on.

Professor Sedgwick said that the bulletin afforded some indication of the kind of work that had been and is being carried on by officers of health, whether medical men or laymen, in the United States.

In a letter from the State Commissioner of Health of Virginia to Professor Sedgwick Dr. E. G. Williams says:—

Before the reorganisation of the State Board of Health the appropriation by the Legislature for two years was \$8000. Now you will notice from the Budget that the appropriation for the two years is a little short of one million dollars. Typhoid has been reduced from approximately 15,000 cases the first year of our work to 3500 last year. We hope it will not be many years before it will disappear.

Professor Sedgwick said that lectures, illustrated by lantern slides, posters, diagrams, and circulars dealing with public health education, were given all over the States. These showed what and how much could be done. He quoted a lecture on Trudeau's work on consumption, wherein the history of the development of a successful sanatorium was traced, and the methods employed with excellent results were described. It was pointed out in the lecture that, as in other sanatoriums, only by training in useful and carefully regulated work could the patients be interested and encouraged, their moral raised, and the disease checked.

Professor Sedgwick's own work as a teacher in training health officers and in connexion with the Massachusetts State Board of Health, his researches on the protection and purification of water-supplies and the purification of sewage, are amongst the most important carried out in recent years, and his contributions to epidemiology in the tracing and stamping out of endemic and epidemic diseases have been of national value. We are grateful to him for coming to give us of his wide and ripe experience, and to his colleagues for sparing him to us for a part of their University session.

INDUSTRIAL BLINDNESS.

THE returns of the civilian after-care department of the National Institute of the Blind show Lancashire to have 4202 sightless persons as compared with 2593 in Yorkshire. This difference is largely due to the character of the industries carried on in the two counties. Mining and steel industries are both highly dangerous occupations, especially with regard to the eyes of the workers. In spite of the attention given by the local authorities to the prevention of such injuries, it appears that the number of those who have lost their sight from industrial causes has increased during the last ten years. On the other hand, the compulsory notification of ophthalmia neonatorum has resulted in a great diminution of infantile blindness.

PUBLIC HEALTH AT CAPETOWN.

THE population of the city of Capetown was estimated to number 172,050 on Dec. 31st, 1918, no increase having occurred during the previous twelve months, the deaths indeed (7892) having exceeded the births (5482). There has been no complete census enumeration since 1911; the European population was estimated at 89,700 in December, 1917, and this estimate is considered to hold good for the next year. The period for which Dr. A. Jasper Anderson, medical officer of health to the city, presents his report is the twelve months ending June 30th, 1919, which he describes as "undoubtedly the blackest year in the annals of the city with regard to the health of the people. The extremely severe epidemic of influenza in October, 1918, has vitiated all the health statistics, and renders all comparisons with previous years fallacious."

The general birth-rate was 31.86 per 1000, that for Europeans being 24.59, and for non-Europeans 39.76, as compared with 35.44, 27.44 and 44.12, the ratios for 1918. The general death-rate was 45.86, that for Europeans being 26 and for non-Europeans 67.48; when corrected for visitors these ratios become 42.38, 22.78, and 63.74 respectively. The European male death-rate was 25.42, and that for females 20 per 1000. In the month of October the deaths numbered 4588,

out of the year's total of 7890; this, when compared with the 245 deaths in October of the year preceding, gives some idea of the influenza visitation. The infant mortality ratio was 224.37 per 1000 births, compared with 152.28 in 1918; for Europeans these ratios were 114.69 and 79.24; October and November were particularly fatal to the new-born infants, 415 dying in these two months out of the total 975 during the year. There was great variation in the different wards of the city as regards this infantile mortality; among European babies 291 per 1000 born died in the Harbour ward (No. 2), but only 42 per 1000 in Kalk Bay (No. 14); while among non-Europeans 397 per 1000 died in Mowbray and 179 in Park ward; this slaughter of the innocents is therefore to a great extent preventable.

Infectious Diseases.

There were 444 cases of enteric fever, of which 234 were among Europeans (2.61 per 1000), with 23 deaths; 85 of these cases occurred in Woodstock and Salt River wards, together with 59 among non-Europeans, making a total of 144 cases in these two wards, which have no drainage system and are overcrowded. Tuberculosis was notified (or discovered) in 709 fresh cases (of whom 129 were Europeans), compared with 830 (of whom 134 were Europeans) in the previous year; the death-rate for Europeans was 0.84 per 1000 (compared with 0.87 in 1917-18). Influenza reached Capetown in September, 1918, and came to an end in the last week of October. It caused 4041 deaths, of which 961 were among the European residents, the death-rate being 10.7 per 1000 for Europeans, 37.4 for natives, and 23.4 for the whole population. Vigorous and successful measures were taken to deal with the epidemic, and inoculation with a polyvalent vaccine was used with good effect. The composition of this vaccine was: *B. influenza* (Pfeiffer) 200 millions, streptococci 1000 millions, and pneumococci 800 millions per c.cm., with a dosage of 0.25 c.cm.

Strenuous efforts for the extermination of mosquitoes continue to be carried out on the usual lines, and "many inhabitants have expressed their appreciation of the comfort derived from the diminution of the annoyance caused by this insect." Rat-catching is also carried out systematically, 6079 having been destroyed in the course of the year. It is noteworthy that only 17 cases of measles, and not a single case either of small-pox or of scarlet fever, occurred in Capetown during the two years, July 1st, 1917, to June 30th, 1919.

The report is fully illustrated by tables and diagrams. It might be suggested that the ward-populations be stated, so that the relative incidence of infectious diseases, &c., in various parts of the city might be ascertained. The mere statement of the number of cases or deaths does not show comparative severity of incidence.

FOOD CONTROL IN GERMANY.

A PARAGRAPH appears in the *Economic Review* (Sept. 3rd) which affords an interesting comparison of the food control position in Germany in certain directions with that in this country. It is as follows:—

An outcry for the release of bread and foodstuffs from Government control is making itself loudly heard. It is stated in the technical organ, *Die Mühle*, that while 25.40 per cent. of the price of 100 kg. of rye goes to the farmer, the Government absorbs 32.60 per cent., mostly in the futile expenses of the official apparatus of control. Bread is now Mk.1 per lb., as against 12 Pfennig before the war, yet the Government operations show a yearly deficit of Mk.4.7 milliards. It is pointed out, however, that a hundredweight of foreign corn costs Mk.500 to 600, and that the present price of bread in Germany is considerably below its value in the world market.

Germany has, no doubt, pushed the policy of subsidising essential foods much on the lines pursued by our Government, and the withdrawal of that policy must, at all events for a time, tend to advance prices. It is to be hoped that the harvests this year will show a good return, and so help to ease the situation.

ANNIVERSARY OF COMMERCIAL AVIATION.

SINCE the Handley Page Pioneer Commercial Air Service was inaugurated a year ago the London to Paris service has been established, so as to necessitate a custom house on the Cricklewood aerodrome. A Royal air mail service from London to Holland was started on July 6th, and another to Belgium on July 19th. In August London was linked up to Berlin, Hamburg, Bremen, Warnemünde, Malmö, Copenhagen and Christiania via Amsterdam. During the period from July 25th to August 31st inclusive 848 passengers were carried on these services. The total number carried from Sept. 2nd, 1919, to August 31st, 1920, inclusive, was 2988, the freight and mails amounted to 149,975 lb., and the distance covered to 213,350 miles. Goods carried ranged from valuable jewellery, samples of goods, to babies' cradles, heavy chemicals, and machinery weighing a quarter of a ton in one piece. Livestock included cats, dogs, fowls, and lobsters. Letters can be sent by air to Paris or Brussels merely by marking them "By Air Mail" in the top left-hand corner and affixing 2d. per ounce extra in stamps.

A POISON IN MENSTRUAL BLOOD.

B. Schick, in the *Wiener klinische Wochenschrift*, No. 19, 1920, records that a bunch of roses held for some time in the hand of a menstruating woman drooped and faded within 24 hours. It appears that the injurious effect on cut flowers of contact with this particular woman had been known to others and some experiments were made on the supposed menstrual poison which is designated by the name "menotoxin." The action is not one common to all women during menstruation. The anemone seems specially susceptible to the supposed poison—this flower held in the hand for 10 minutes by the person experimented on faded in four hours, and the effect was most marked during the first 24 hours of menstruation. Even the activities of yeast in dough were said to be affected. The medium of the assumed poison is the sweat. If the flowers were held in the hand encased in an indiarubber glove they were unaffected, nor were they affected by being vigorously breathed on or by the saliva. A swab of the sweat taken from the axilla or palm of the hand placed in a vessel of water containing flowers acted on them in the same way as did contact with the hand. The serum of the menstruating individual was inactive, while the blood-clot was markedly poisonous. Menstrual blood itself has proved to be highly poisonous to flowers and twigs; its poisonous activities were not affected by heating to 56° C., and were only slightly weakened after heating to 100° C.

ANÆSTHETICS IN VETERINARY SURGERY.

In his presidential address recently delivered at Bristol before the members of the Mid-West and South Wales Veterinary Association Mr. W. M. Scott, F.R.C.V.S., pleaded for organisation in the veterinary profession to attain the objects which all veterinary surgeons desired. The Animals (Anæsthetics) Act, recently added to the statute-book, had lost at the eleventh hour its most important clause—namely, that no anæsthetic should be administered unless by a duly qualified veterinary surgeon. The object of the promoters of the Bill had been to obliterate surgical pain. Could anyone, he asked, imagine anything more incongruous than the empiric, who had had no collegiate training, administering an anæsthetic to produce complete anæsthesia? Imagine a human being chloroformed by a barber! The animal might have a whiff of chloroform, but who was going to prove that the operation was painless? Mr. Scott added with regret that the unqualified element which resisted the Bill was a stronger and better organised force than that representing the veterinary profession itself.

DRY CELLS AND BATTERIES.

Messrs. Siemens Brothers and Co., Ltd., of Woolwich and Palace-place-mansions, Kensington Court, W., have just issued a new and enlarged edition of their catalogue of dry cells. The list is a very comprehensive one, the number of types and sizes manufactured at their factories exceeding 600. The applications are, of course, numerous; but amongst the cells described are those adapted for medical work, such as galvanisation, faradisation, ionic-medication, galvanocautery, exploring lamps, and so forth. The portability of these cells is an obvious advantage in medical practice. The list includes also specifications of "inert" cells, which may be stored, it is claimed, for an indefinite period in any climate without undergoing deterioration. The cell is rendered active by the addition of water. This form of cell offers a clear convenience.

EYESIGHT AND SHOOTING.

THE anxiety of the Germans about the good shooting of their army, their determination that all soldiers should have their errors of refraction corrected by "shooting spectacles," and that breakages, if they occurred, should be immediately replaced are well brought out by Major R. A. Fenton in the *Military Surgeon* (Washington, D.C., U.S.A.) for July. An "optical chest," holding 208 pairs of lenses and 84 empty spectacle frames, was carried by every division and even up into the front line. Men with uncommon defects had a duplicate pair of lenses supplied them before leaving Germany (the prescription was pasted into their pay books), and the medical officers of their units were responsible that these spare glasses were on the men or replaced. German ametropes wore special spectacles inside their gas masks, but Americans wore theirs outside. The German lenses were 38.2 mm. in diameter, the American 40 mm., which made a little awkwardness when the United States army captured German stores and wanted to use the spare lenses found in their own spectacle frames. The lenses were very often menisci to diminish distortion in the periphery of the field. The loss of useful service of soldiers whose spectacles were broken was considered at headquarters to be so important that replacements in the optical chest were demanded immediately by post and by post issued from headquarters in Germany directly. We have little doubt that our army had no such detailed arrangements for helping ametropes.

STERILISED HORSE SERUM.

THE treatment of anæmia by the internal administration of horse serum has been studied in France. The serum is also a hæmostatic agent applicable in external and internal hæmorrhage. Dr. Émile Weil has lately mentioned it in this connexion (*THE LANCET*, August 7th, p. 300). Hémostyl (L. Preud'Homme, 21, Rue d'Aumale, Paris) appears in three forms: (1) fluid in ampoules; (2) syrup; and (3) tablets. Samples have recently been submitted to us. It is stated that hémostyl is collected from young and healthy animals frequently bled, each drawing being carried out at a time when the horse is at the maximum point of blood regeneration. The treatment is based on the idea of "la rénovation sanguine." There is an extensive bibliography on the subject, published in Paris, Lille, Montpellier, Bordeaux, and elsewhere, and a paper by P. Carnot is quoted entitled, "Thérapeutique des syndromes hémorragiques" (Rapport au XIII^e Congrès français de Médecine, Octobre, 1912). The use of horse serum in sepsis is referred to also in an annotation in *THE LANCET* of June 12th, 1920, p. 1279. Samples of hémostyl may be obtained from Messrs. Wilcox, Jozeau, and Co., 49, Haymarket, London, S.W. 1.

ROYAL EARLSWOOD INSTITUTION FOR MENTAL DEFECTIVES.

We congratulate the board of management of this benevolent institution on its relief from financial embarrassment owing to a bounteous bequest from an old supporter, which will enable the clearing off of a bank overdraft amounting to £20,000, "contracted largely owing to the conditions prevailing during the great war," as well as the carrying out of much-needed improvements delayed through lack of funds. The seventy-third annual report of the institution, from which we take this gratifying information, shows that over 4000 cases have participated in the benefits of the establishment since its foundation in 1847, benefits not confined to the inmates themselves, but affording incalculable relief to families burdened with a mentally afflicted member. Earlswood has all along ministered to the needs of various social ranks and conditions, and now that public provision by local authorities and the State is to be made more largely under the Mental Deficiency Act the board of management contemplates an extension of the scope of usefulness of the institution to the needs of the professional and middle classes, impoverished as they are by present financial conditions, so as to entitle them to consideration in the scheme of charitable aid for mental defectives. Experience has shown that in the majority of cases permanent supervision is desirable, and the fact that more than half of the inmates of Earlswood are now over 20 years of age, and that 72 were on Dec. 31st, 1919, 45 years and upwards (three being over 75), shows that this desideratum has not been overlooked, though still capable of extension. At the same time, in order to secure the best results from training early admission is essential, and the proportion of those admitted last year under 14 years of age was 65 per cent., amongst them three infants under 5. From the report of the medical superintendent (Dr. Charles Caldecott) for 1919 we glean the following particulars. The aggregate of cases under care during the year numbered 522 (339 males, 183 females), and the average number in residence 446 (280 males, 166 females). Of 67 cases admitted, 11 were classed as idiots, 50 as imbeciles, 1 feeble-minded, and 1 moral imbecile. Eight were "Mongolians," 2 hydrocephalic, 9 epileptic, and 10 paralytic. Of 37 patients discharged, 30 were notified as "improved." Fifty deaths occurred during the year, 15 attributed to influenza, 13 to various forms of tuberculosis, and 4 to senility (the oldest aged 76). Post-mortem examinations were made in 34 cases. The death-rate, equivalent to 11.2 per cent. on the average number resident, is more than double that occurring in pre-war times, and Dr. Caldecott states that during the last three years there have been severe epidemics and unusual debility due, he thinks, to unfavourable war conditions, such as restrictions of diet and interference with normal lighting and ventilating arrangements necessitated by D.O.R.A. regulations. He considers, however, that, in view of the proportion of inmates normally requiring hospital care being at least 25 per cent., infirmary additions are called for, and he suggests balconies for open-air treatment.

The report contains interesting details as to the instruction of the patients, both at school and in a variety of useful indoor and outdoor industries. In such an institution there must needs be also much of medical interest, and we are glad to find that facilities for the clinical study of mental deficiency are afforded to students of metropolitan hospitals and post-graduate classes.

Dr. G. K. Audrey has been appointed chief assistant medical superintendent to the institution.

THE offices of the Director-General of Medical Services, Ministry of Pensions, have been transferred to the Crown Agents' Annexe, 5, Millbank, Westminster, London, S.W. 1.

The Humbleian Lectures

ON THE

CLINICAL EXPERIENCES OF A PHYSICIAN DURING THE CAMPAIGN IN FRANCE AND FLANDERS, 1914-19.

Delivered before the Royal College of Physicians of London

BY SIR JOHN ROSE BRADFORD, K.C.M.G.,
C.B., M.D., F.R.S., F.R.C.P.

LECTURE II.*

JAUNDICE.

MR. PRESIDENT, FELLOWS OF THE COLLEGE, AND GENTLEMEN,—Several interesting clinical types of jaundice were seen, although these maladies never assumed in France and Flanders the proportions attained in the other seats of war, and no very large numbers of cases of jaundice of any type were seen at any period of the campaign. The most common type of jaundice seen was that usually diagnosed as so-called catarrhal jaundice, an ill-defined clinical group presenting considerable variations in its clinical symptoms; but, of course, a considerable number of cases of jaundice occurred as a complication of the more serious forms of the septic infection of wounds. In addition to these varieties, however, certain other distinct types were seen, one in association with infections of the enteric group, a second apparently connected with influenza, and a third the interesting form dependent upon spirochaetal infection and now known as spirochaetal jaundice. This malady is regarded by some as identical with the disease formerly described as Weil's disease, although probably not entitled to this name: by others the two affections are thought to be distinct and separate, as the clinical phenomena of the reported cases of the two maladies present some differences. Jaundice was seen as an occasional complication of other infections. Thus a very severe type was seen as a rare complication of pneumonia; but I wish more particularly to discuss the other varieties mentioned above. In addition to the forms of jaundice arising as the result of disease or as the sequel to wounds, a certain number of cases of toxic jaundice of a very severe type and very frequently fatal occurred as a complication in the treatment of syphilis with arsenical compounds.

Jaundice the Sequel of Wound Infection.

Two principal varieties of this form of jaundice were seen: firstly, the well-known jaundice accompanying severe streptococcal infections; and, secondly, that associated with infections dependent upon anaerobic bacilli. It cannot, however, be asserted that in the latter instances such anaerobic bacilli were the only organisms present. It would be more correct to speak of the streptococcal cases as free from the presence of gas-forming bacilli and the anaerobic cases as examples of mixed infection in which, however, the anaerobes were the important element.

Jaundice associated with streptococcal infections.—The jaundice associated with streptococcal infections was of very varying degrees of intensity—sometimes a mere icteric tinge, in others a jaundice of a very marked and bright yellow colour. Such cases, even when very severe and ultimately fatal, often ran a rather prolonged course, and, so far as my experience went, were not characterised either by the invariable association of severe nephritis or of marked hæmorrhagic complications with the jaundice. In these respects they presented a marked contrast to the cases of jaundice dependent upon anaerobic infections. These streptococcal cases then only showed the clinical picture of jaundice of varying degrees of intensity, although the mere presence of this complication greatly increased the gravity of the outlook.

Anaerobic jaundice.—The cases of anaerobic jaundice were much more remarkable in several respects and often presented problems of considerable difficulty from the clinical point of view. The onset and development of the jaundice in these cases were often extremely rapid and the depth of colour most remarkable; generally it was an extremely deep yellow, but sometimes it was definitely a deep orange greatly resembling that seen in spirochaetal jaundice.

Some of the most marked examples of anaerobic jaundice were seen in cases where the anaerobic infection was not an immediate complication of the wound, but where it ensued after a latent period of varying length. Thus it might perhaps be best studied in cases of hæmothorax with anaerobic infection, but where this anaerobic infection either only developed some few days after the infliction of the wound, or, at any rate, where it only developed to a serious degree after such a period of latency. One of the most striking clinical features of this variety of jaundice is the extremely rapid development of the jaundice once it is present; thus one day the patient may present only a doubtful icteric tinge of the conjunctiva, but in some 24 hours the skin has become deep yellow or even orange in colour. Secondly, a considerable amount of nephritis is generally, if not invariably, associated with the icterus, and the urine contains not only much albumin but also casts, granular and hyaline. Thirdly, a purpuric condition develops early and more especially epistaxis and hæmatemesis. In the less severe cases the hæmatemesis is probably only dependent upon the vomiting of blood derived from epistaxis, but in the more severe cases true hæmatemesis may occur.

Although this variety of jaundice is always very formidable and often fatal, this is not so always if its true nature is at once recognised and prompt measures are taken to deal with the infection. In cases of gunshot wounds of the chest with hæmothorax the true nature of these cases is very apt to be overlooked. It is not always realised that the development of jaundice of this type is really proof that the hæmothorax is not a simple but an infected one, and that the infection is one due to anaerobes and calling for instant treatment. Such cases are apt to be misunderstood and the jaundice attributed to a supposed wound of the liver, the hæmothorax being regarded as merely part of a more serious lesion, whereas in reality it is the sole lesion. Such mistakes are especially prone to be made when the wound is in the lower chest and on the right side, but so many chest cases are seen where there is only an entry wound and the course and even the position of the foreign body are unknown that this error is by no means limited to cases where the wound of entry is in the hepatic region. It is very doubtful whether wounds of the liver ever cause jaundice unless the wound is infected, but there is no manner of doubt that chest wounds on the right side, where the liver can be shown on post-mortem examination to have been uninjured, may be complicated by the most intense jaundice if the hæmothorax present is infected with anaerobes and gas-forming organisms. This anaerobic jaundice presents considerable resemblances to the jaundice of the more severe forms of so-called Weil's disease, or more correctly of spirochaetal jaundice, more especially in the depth of colour of the icterus, the degree of nephritis present, and the tendency to purpuric hæmorrhage; but so far as my experience went the conjunctival injection, herpes, and a certain peculiar muscular tenderness, all very characteristic features of spirochaetal jaundice, are not found in anaerobic jaundice.

Jaundice as a Complication of Definite Infections.

Jaundice as a complication of certain definite and well-known infections was occasionally seen, but although this clinical variety occurred in such diseases as pneumonia, enteric fever, and in influenza, it was not a common complication, and in the cases of enteric fever, and especially in influenza, the diagnosis was often by no means certain.

Jaundice certainly occurred as a complication of pneumonia even when the causative organism was shown to be a pneumococcus. Usually it was not of a severe type; such patients might have a citron-coloured sputum and slight icterus, conjunctival and cutaneous. I only saw one case of intensive jaundice complicating pneumonia, and here the organism was a pneumococcus of Type II., and the case was fatal, with massive pneumonia involving the whole of the right lung. A few cases of jaundice of moderate severity were seen that were regarded as being in all probability of influenzal origin. These cases were characterised by the sudden onset of a febrile illness with a temperature of 102° or 103° F., intense headache, and general aching pains in the limbs. The pyrexia lasted only a few days, and its subsidence was often accompanied with much sweating, and was followed by the development of jaundice of moderate severity, the colour of the skin being a bright yellow, lasting some

* Lecture I. appeared in THE LANCET, Sept. 11th, 1920 (p. 535).
No. 5064

two to three weeks. Such cases had no splenic enlargement and no evidence of nephritis beyond in some cases a minute trace of albumin in the urine. They were regarded as possibly influenzal in origin as they showed no evidence of infection with either organisms of the enteric group or with spirochaetes. Clinically they resembled cases of so-called catarrhal jaundice except that the symptoms at the onset were more severe and the febrile period more marked and prolonged than is usual with catarrhal jaundice. It is remarkable that such cases were not only seen when there was an undoubted epidemic of influenza prevalent, but also that they occurred at other times when such was not the case. It is, of course, quite possible that this variety of jaundice was in reality due to some other and possibly unknown infection. In the severe and undoubted outbreaks of influenza that occurred in 1918 and 1919 jaundice was not a common complication.

The relation of jaundice to the infection produced by the enteric group raises several difficult clinical problems that are not, perhaps, completely settled. In the first place jaundice was not often seen as a complication of undoubted cases of enteric fever; whether this was due to infection with the typhoid bacillus or with one or other of the paratyphoid organisms; and this is in harmony with the experience of civil practice, where such a complication is also admittedly rare. On the other hand, a certain number of cases of febrile jaundice with splenic enlargement as a leading feature of the illness were seen, and in some of these cases the pyrexia was often prolonged and of a type similar to that seen more especially in paratyphoid infections. Such cases also usually showed evidence of the presence of some nephritis, as the urine contained a small or moderate amount of albumin, always more than a mere trace.

In these cases the jaundice was very marked, sometimes intense and always an early feature of the illness, coming on within the first week of illness and not uncommonly so early as to be the first sign of the presence of illness. In other words, the jaundice was not a complication of an existing illness, but rather an early manifestation of such illness, and sometimes actually an initial manifestation. No fatal case fell under my observation, and thus post-mortem evidence of their nature is lacking; but bacteriological evidence was in some, but not in all, in favour of this variety of jaundice being due to infection with organisms of the paratyphoid group. This evidence was usually only that afforded by an agglutination test, and such evidence is not always really conclusive, as there are numerous possible fallacies and some technical difficulties.

The fact remains that there was a small group of cases of febrile jaundice with definite and sometimes considerable splenic enlargement and moderate albuminuria; that in such cases the jaundice was an early and prominent feature of the illness; and that in some, but not in all, there was some evidence that possibly such cases were due to infection with organisms of the enteric group, limiting their activities to infection of the biliary passages and not producing ordinary enteric fever. It is, however, by no means certain that all cases of this clinical type belonged to this group, and it may well be that there are other infections affecting primarily the biliary passages. Nothing comparable to the serious outbreaks of jaundice reported as due to paratyphoid infection that have been described as occurring in other fields of war—e.g., Gallipoli—occurred in France and Flanders.

SPIROCHÆTAL JAUNDICE.

Perhaps the most interesting variety of febrile jaundice seen in France was that dependent upon spirochætal infection. There is some confusion in nomenclature with reference to this disease owing to the doubt whether these cases are the same type as the disease formerly described under the name of Weil's disease. There are considerable clinical resemblances between the two maladies, but also some differences, more especially in regard to the condition of the spleen, enlargement being stated to be much more frequent and characteristic of the one than of the other. The malady to which Weil's work directed attention was known as one liable to occur in armies, and hence from the earliest period of the campaign watch was kept for any cases of jaundice of doubtful origin; but the first case I saw of this disease occurred in a Canadian in December, 1915. A moderate number of cases came under observation in 1916, and in the subsequent years, 1917 and 1918, a smaller number was seen. The clinical picture presented by a severe case is so distinct and characteristic that the

malady can scarcely be overlooked by anyone familiar with it; but in the slighter forms this is not the case, and it may then not only be readily confounded with some of the more severe forms of so-called catarrhal jaundice, but even with quite mild forms of the latter disease.

Distinctive Features.

There are many distinctive features in spirochætal jaundice, but they do not demand more than short mention here, as several descriptions of the malady have now appeared in medical literature.

In cases of moderate severity the disease is of sudden onset, with considerable pyrexia, the temperature rising to 102° or 103° F., or more, the fever lasting generally about ten days, sometimes more, and in slight cases sometimes less, and then returning rather suddenly to the normal, but without a distinct crisis. A most characteristic feature of the temperature chart is the occurrence of a secondary rise of temperature or relapse lasting only two to four days, and taking place within a week of the subsidence of the initial pyrexia. This secondary rise is not always present, and may be absent in the cases of the greatest severity that are fatal, as is not infrequently the case in the earlier stages of the illness. It is, however, not uncommon in quite mild cases, and affords one of the means of distinguishing these mild cases of spirochætal jaundice from similar mild cases of so-called catarrhal jaundice. The jaundice is remarkable for its great intensity in the severe cases and for the frequency with which it is of a deep orange colour, a depth and variety of colour that was not familiar to me in civil practice. With the subsidence of the pyrexia the jaundice begins to diminish, and it is of interest that the relapse with the recrudescence of fever is not accompanied with any corresponding increase in the jaundice.

Another extremely characteristic feature of the illness, but perhaps not present in all cases, is not only the occurrence of severe muscular pains during the earlier periods of the pyrexia, but also the presence of very considerable muscular tenderness.

This tenderness of the muscles is especially marked in the muscles of the thighs and of the abdominal walls, but sometimes it is more widespread and may affect also the arms. The pain in, and especially the tenderness of, the abdominal recti and of the thigh muscles was not uncommonly so great as to require cradles to keep off the pressure of the bed-clothes. This muscular tenderness was not limited to the severe and fatal cases; it may be quite marked in cases of very moderate severity, and again affords a useful diagnostic criterion. I know of no other variety of jaundice where such a phenomenon as this is present. Although no gross changes are obvious clinically to account for the extreme muscular tenderness, examination of the muscles from a fatal case, in the first instance by Captain Pringle, R.A.M.C., and subsequently in several other fatal cases by Captain E. F. Bashford, R.A.M.C., revealed the presence of very distinct lesions both degenerative of the muscle fibres and interstitial, the latter of an inflammatory nature with hemorrhages. The details of this muscular lesion will, it is hoped, be published later. This muscular lesion, both clinically and pathologically, is a very characteristic feature of the malady, and is certainly usually, if not invariably, present. It is a useful clinical sign both in severe and in mild cases. In the former it may assist in differentiating jaundice dependent upon spirochætal infection and that seen after salvarsan and similar compounds. In mild cases it may assist in differentiating between spirochætal and catarrhal jaundice. Similar muscular lesions are present in the guinea-pig after inoculation with the blood derived from human cases during the early pyrexial period. It is curious that the symptoms caused by the muscular lesions in spirochætal jaundice should be so severe, since the much more obvious muscular lesions occurring occasionally in other infections—e.g., influenza, enteric fever—are often not associated with very marked clinical symptoms.

Purpura in some form is another characteristic feature of the spirochætal jaundice; the purpuric eruption on the skin is often scanty and the spots small, but other purpuric phenomena are common.

Thus an outbreak of labial herpes rapidly becoming hemorrhagic is of very frequent occurrence and bleeding from the gums is common, leading to the presence of masses of decomposing blood clot encrusting the teeth. Epistaxis is also very common and severe hæmatemesis is often the immediate cause of death. Hæmatemesis may be scanty and repeated, but several instances were seen where the first hæmatemesis was of large amount and either rapidly or even immediately fatal. In a few instances such fatal hæmorrhage occurred in cases where up to the time of its occurrence there had been no symptoms that seemed to warrant such a grave prognosis.

Nephritis is a very constant accompaniment of spirochætal jaundice, and the amount of albumin present is usually considerable and may be large.

In the mild cases the albuminuria is often transitory in duration, lasting only a very few days, whereas the jaundice, even in the mild cases, may last three to four weeks. The nephritis is not accompanied by dropsy so far as my experience went, even when it was of a very severe type, but the urine may become very scanty or the secretion even may be suppressed. In the cases where purpura is marked profuse hæmaturia may be present similar to that seen in the most severe forms of purpura hæmorrhagica, and such cases may also suffer from hæmorrhage from the bowel and from hæmoptysis. It is difficult to say to what extent the severe and fatal cases suffer from uræmia, but such patients become very prostrate, lethargic, and apathetic, and may be partially or even completely unconscious, with a subnormal temperature for several days before death. It is difficult if not impossible to say how far these symptoms are uræmic and how far they are cholæmic in origin.

Another remarkable feature of the disease is the frequency of pulmonary lesions and of pulmonary complications, more especially areas of lobular pneumonia with the expectoration of a sanguinolent sputum.

On post-mortem examination areas, often of some size, of imperfect consolidation, together with extreme congestion and hæmorrhagic infiltration, are found and are very characteristic features of the morbid anatomy of the disease. Herpes (labial) and purpura are not the only rashes seen. Sometimes there is a most remarkable roseolous rash, each spot being one-third of an inch in diameter and of an intense bright red colour and distributed all over the trunk and limbs. The appearance of the patient is most striking owing to the contrast of the bright red rash on the background of deep orange jaundice. Such rashes have not apparently any grave prognostic significance.

The conjunctival congestion that is seen in the earlier stages of the disease is also a very characteristic clinical sign.

The clinical features of a severe and especially of a fatal case of spirochætal jaundice are then very marked and characteristic. A febrile onset with marked muscular pains and local muscular tenderness, intense jaundice often orange in hue, herpes labialis, and especially hæmorrhagic herpes affecting the lips and face, purpura, possibly markedly hæmorrhagic in character, nephritis and great prostration, together with much vomiting—all these form a very definite and characteristic clinical picture not presenting any very close resemblance to other diseases met with in temperate climes.

Diagnosis.

The diagnosis of well-marked cases is therefore not usually difficult, although sometimes it may not be easy to exclude at once the possibility of the presence of one of the more severe forms of toxic jaundice such as that due to salvarsan, or that due to phosphorus, and I have seen one case of spirochætal jaundice where the extreme congestion and hæmorrhagic condition of the mucous membrane of the stomach was quite comparable to that seen in phosphorus poisoning. It is sometimes possible to detect the spirochæte in human cases by direct examination of the blood, but a much more reliable method is to inoculate a guinea-pig with a small quantity of blood from the suspected case during the febrile period of the illness and before the eighth day of the disease. The spirochæte can be found with far greater ease in the experimental animal after the reproduction in it of the disease. Further, the spirochæte can be recovered from the urine in the human subject during a prolonged period in marked contrast to what obtains in the blood, as there it can only be found in the earlier days of the disease. The detection and recovery of the spirochæte from the urine present, however, certain technical difficulties that need not be considered here as they are dealt with in the papers by several authors describing this disease and its diagnosis. Whilst there is no great difficulty in recognising the more severe forms of the disease, there can be but little doubt that a certain, and perhaps a considerable, number of cases are looked upon as merely cases of so-called catarrhal jaundice.

In these milder cases the febrile onset is of less severity and the fever persists for a few days only, so that not infrequently the jaundice is not noticed until the pyrexia has disappeared. In this respect these cases resemble not only cases of catarrhal jaundice, but also cases of post-influenzal jaundice, and the resemblance to this latter disease may be

still greater owing to the presence of limb pains in both of them. The jaundice in the mild cases may only be of moderate intensity, although even in these it is usually more marked than in the average case of catarrhal jaundice. The nephritis also may be slight and transitory, so that clinically it may be impossible to distinguish these mild cases from catarrhal jaundice unless the observer is fortunate enough to see the case in the first week of illness or whilst pyrexia is still present. Then by inoculating a guinea-pig with blood from the patient the spirochæte can be recovered, even in cases of very slight severity, and their true nature established.

There are two clinical points that may be of assistance in the diagnosis of even these mild cases, and are sometimes sufficient to separate these cases from catarrhal jaundice—i.e., the presence of the muscular tenderness and the occurrence of the febrile relapse. Both these phenomena may occur in quite slight cases of spirochætal jaundice. The difficulty in the diagnosis of these slight cases must necessarily be considerable, because the organism can only be recovered from the blood in the early stages, and as at this stage jaundice may be absent the full examination of the blood is not made, as the malady is not suspected. Hence the pyrexia, particularly as it is transitory, is attributed to some such cause as supposed influenza, and then when the jaundice supervenes it may be too late to detect the spirochæte in the blood.

How many cases of supposed catarrhal jaundice or of post-influenzal jaundice are [really of spirochætal origin I am unable to say, but I am inclined to think that in all probability it is appreciable, as we recovered the spirochæte from the blood in several cases indistinguishable from catarrhal jaundice in the trivial character of the illness, but here we were fortunate in seeing the patient early in the illness. Nevertheless, in many cases we failed. Doubtless catarrhal jaundice is not a definite clinical entity; rather it includes probably a number of conditions of different nature and of different origin—some of cholangitis, some of duodenitis, possibly some of pancreatitis, although perhaps cholangitis of some kind is answerable for the majority of cases. Further, it would seem that at present we do not know the real causation of the bulk of cases of catarrhal jaundice. From its clinical course it would seem to be an infection, but no causative organism has as yet been found, and no spirochæte has been found in the great majority of cases examined. Further, although there is a general resemblance in the clinical picture of all cases of catarrhal jaundice, yet there are individual differences that are very difficult to understand. Are these dependent upon mere variation in the intensity of the lesion, or are they due to quite different and separate varieties due to different causes? Thus all observers would agree that some cases, indistinguishable at the outset from ordinary mild catarrhal jaundice, after a few days' illness suddenly run a totally different and rapidly fatal course, with the sudden rapid development of dangerous symptoms such as hæmatemesis or cholæmia. The observations made in France showed that such cases might be spirochætal in nature and, further, that all mild cases of spirochætal origin did not necessarily follow such a course.

Thus, in so far as spirochætal jaundice is concerned, it would seem that profound differences in clinical type were still consonant with one and the same cause, and did not necessarily indicate different ætiology. There are, however, differences seen in any large series of cases of catarrhal jaundice that are difficult of explanation as merely the result of differences in the severity of the infection. To mention only two, the incidence of nephritis in catarrhal jaundice and the presence or absence of splenic enlargement. So far as my experience goes in the observation of considerable numbers of cases of catarrhal jaundice, the severity of the illness and the degree of jaundice can certainly not be correlated with the degree of albuminuria present or with the presence of splenic enlargement. Some cases of so-called catarrhal jaundice have marked enlargement of the spleen and some had considerable albuminuria; others did not, and this could not be correlated either with the severity of the illness or with the presence of some definite infection such as a spirochæte or organisms of the enteric group. The fact that some cases of mild simple catarrhal jaundice yielded under favourable conditions evidence of the presence in the blood of a spirochæte suggests that this group of cases is not a single clinical entity and that probably many owe their origin to some unknown specific agent.

NEPHRITIS.

The study of this disease during the war has yielded some facts of interest both from the point of view of ætiology and of clinical medicine, and it affords a striking example, showing how the clinical phenomena

of a thoroughly well-known malady may apparently be different to those usually described when the disease is seen on a large scale and under conditions different to those we were accustomed to. All physicians very soon realised that the clinical phenomena of nephritis as seen in France were somewhat different to those familiar to them in civil practice. Some attributed this to the supposed occurrence of a new disease and so labelled it "trench nephritis," now modified to "war nephritis." Others were not so confident that the differences, such as they were, might not be more correctly attributed to the different conditions under which the disease occurred.

In my first lecture I drew attention, in discussing acute rheumatism, to the efficiency with which the medical examination of the troops had been carried out in this country prior to their departure overseas and to the rarity with which organic diseases such as valvular disease of the heart were met with. The same is true of other chronic or latent diseases, and the rarity of chronic renal disease in the original Expeditionary Force and in the subsequent armies sent over to France was very striking.

The Small Contracted White Kidney.

Thus cases of such an insidious malady as chronic nephritis in its various forms were quite infrequent, although a few examples of that remarkable condition, the small contracted white kidney of young adults, were seen.

It is a very extraordinary fact that men suffering from such a lesion as this should have been able to withstand even for a time the hardships, fatigue, and rigours of the campaign. Several instances of this disease were met with, precisely similar in their clinical course to those seen in civil life, in that the patient only reported sick with the onset of the terminal uræmic manifestations. In one such case the man had gone through all the hardships and fatigue of the earliest stage of the campaign and had fought through the first battle of Ypres, yet he suffered from the typical form of the disease, dying from acute fulminating uræmia, and the kidneys together weighed little over three ounces.

Several similar instances of this condition were seen throughout the campaign, and in all cases death resulted from acute uræmia.

The Occurrence of Nephritis in the Spring of 1915.

These cases of chronic renal disease, although of interest, were so few in number that they were of little importance and no appreciable number of cases of nephritis occurred until the spring of 1915. This is the first fact of interest with reference to this disease because the autumn of 1914 was cold and very wet and the troops suffered greatly from hardships of various kinds, associated with the heavy fighting of the period and the great exposure of the men in the earliest days of trench warfare. They also suffered much from fatigue owing to their long periods of stay in the trenches and the paucity of reliefs. Nevertheless, nephritis practically did not exist. In March and April, with the advent of spring, cases of nephritis suddenly became more common, and in a short time it became obvious that the cases were occurring in considerable numbers, although at no time were the numbers such as to cause anxiety from a military point of view. It may be of interest to recall that about this time what was subsequently known as trench fever first began to attract attention. The first cases of nephritis that came under my observation occurred in March, 1915, and the first cases of pyrexia of an unknown type, subsequently recognised as trench fever, in May, 1915. Trench fever is a disease that might be readily overlooked or confounded with other maladies, but this is not so with nephritis, and there can be little doubt that the malady was not prevalent until the spring of 1915.

The disease affected all branches of the Service, men in the fighting line belonging to all arms, men on the lines of communication, and, what is especially important to note, men such as hospital orderlies who had never left their base hospital. Thus, one hospital unit in Boulogne had four cases at one and the same time amongst their orderlies, men who on leaving England had been nowhere in France except their hospital, a building in the town of Boulogne. Emphasis is laid on these facts because it was only in the early years of the war that such facts could be elicited; later on men were moved about to such an extent that no such observation as

the above was possible. Whilst men belonging to all branches of the Service were affected, the number of officers affected was extraordinarily small, and this was true for the whole campaign. A few cases occurred in women, more especially in nurses.

Immunity of Indians.

The most remarkable fact, however, is that the disease did not occur in the Indian native troops. The large Indian native hospitals, with a total of several thousand beds, were in the area of my work and I paid them constant visits. I saw no case of nephritis and I was informed that only three cases of nephritis had been returned from the whole Indian contingent, and this included one of obvious chronic disease in a native officer some 42 years of age. Thus, at a time when the disease was increasingly prevalent in the British troops it did not occur in the Indian troops.

Although the Indians did not suffer from nephritis, nevertheless they suffered grievously from other diseases attributable to exposure. Bronchitis and pneumonia of various types were extremely common and also of considerable severity, and large wards were entirely filled with such cases. This immunity of Indian troops to nephritis is a striking example of the complexity of the problem of the causation of this disease. Approximately 10 per cent. of the cases of nephritis yielded a history of some antecedent illness, such as a severe cold, diarrhoea, influenza, or sore throat, and doubtless the percentage was really higher as such antecedent illness is often slight and overlooked by the patient. On the other hand, a considerable number of patients, 30 per cent. in a series of 278 cases, either gave a history or had distinct signs of bronchitis when admitted to hospital. Were it not for the fact that the Indians suffered from bronchitis to a very serious degree, but did not develop nephritis, it might be concluded that the frequency of such respiratory affections was an aetiological factor of some importance in the production of the disease.

It is important to realise that the respiratory affection was present in cases of primary nephritis—that is to say, in patients admitted to hospital on account of the renal lesion, and not on account of the bronchitis. Stress is laid on this point, because during the winter of 1916-1917 the nephritis statistics of the army were swollen by the inclusion of large numbers of cases of secondary nephritis, where the renal lesion was merely a complication of severe bronchitis and of lobular or broncho-pneumonia—both of these diseases were prevalent and very severe at that time. Although nephritis was present in these patients and was a common lesion in the fatal cases, such cases do not belong to the same group as those of primary nephritis, and the clinical effects are quite different. Thus this secondary nephritis is mainly characterised by the excretion of scanty urine, with a variable but usually small quantity of albumin. The inclusion of these cases of secondary nephritis also vitiated the mortality statistics, inasmuch as these patients had a high mortality dependent upon the severe character of the primary respiratory disease. In the cases of true or primary nephritis a history could be obtained in some 10 per cent. of the patients of their having suffered at some previous time from a similar attack or that they had been under treatment for "inflammation of the kidneys" or for "Bright's disease."

It is probable, therefore, that in at least 10 per cent. of the cases the patients had suffered from a previous attack of nephritis; this result was obtained from personal investigation of a series of 571 cases. It is difficult to determine what proportion of the patients apparently suffering from primary acute nephritis were in reality suffering from an acute exacerbation of a chronic lesion. That this was so in a certain proportion of cases is evident from the post-mortem findings, as it was not uncommon to find distinct and unequivocal evidence of old-standing lesions in cases where on clinical grounds the malady had been regarded as acute. In a series of 149 cases personally examined a markedly raised blood pressure and apparent hardening of the radial artery were present in 27 per cent.; but it is quite certain that these phenomena were not in all cases evidence of the existence of chronic disease, as such changes may occur quite rapidly as the result of primary acute nephritis. It is, at any rate, certain that the bulk of the cases of true nephritis occurred in men that had not suffered from previous renal disease, and, further, that the nephritis was not constantly the sequel of any severe immediately antecedent illness. On the other hand, a considerable proportion of the cases yielded evidence of having suffered from a trivial illness or presented slight signs of such illness, more especially in, but not limited to, the respiratory tract.

The Influence of Age on Aetiology.

The study of nephritis in the army afforded an opportunity of determining the influence of age in the aetiology of the disease, and 2297 cases were analysed

from this point of view in 1915-1916. These were all cases of primary nephritis, 50·2 per cent. of the cases occurred in men under 30 years, 72·7 per cent. in men under 35 years of age, 15·5 per cent. in men between 35 and 40 years, and 11·8 per cent. in men over 40 years of age. It is therefore clear that the disease is by no means limited in its incidence to the older men, as more than 25 per cent. of the cases occurred in men under 25 years and nearly 75 per cent. in men under 35 years of age.

Colonel Hume has published some statistics of the ages of a body of 3000 hospital patients, from which it would appear that 78 per cent. of these men were under 35 years of age, figures closely resembling the above nephritis results.

Features of Clinical Interest.

Clinically the cases presented many features of interest, and their study may perhaps lead to the modification of some of our conceptions of this disease, and more especially perhaps our views as to the gravity of nephritis. The onset of the disease might be either gradual or apparently sudden, and when sudden the earliest symptoms might be dyspnoea, either nocturnal or produced by exertion—e.g., on the march, dropsy, or pyrexia with hæmaturia. Some of the cases of sudden onset with dropsy also had slight pyrexia, but in all febrile cases the fever was slight and of short duration.

There is a remarkable group of cases to which I alluded in a first paper in the *Quarterly Journal of Medicine*, vol. ix., January, 1916, characterised by rather profuse hæmaturia and pyrexia with no dropsy. The curious feature of these cases first seen in the spring of 1915, and then later throughout the campaign, was the fact that after the subsidence of the initial pyrexia recurrences of pyrexia consisting of a single spike on the chart, and lasting only a few hours and accompanied with hæmaturia, would take place. The temporary character of the fever and the sudden hæmaturia were very similar to that seen in cases of renal embolism. The charts presented considerable resemblance to those subsequently described in one form of trench fever, but there does not seem to be any sufficient ground for regarding these cases of nephritis as really associated with trench fever. These cases of hæmorrhagic nephritis were on the whole uncommon, and formed only a small proportion of the total cases. It was exceptional for dropsy to occur, and the prognosis was good as they generally cleared up in a short time. In the more common variety of the disease pyrexia was either absent or was only present to a slight degree in the earliest stages of the malady. Clinically dyspnoea was a leading feature of the illness and dropsy of the usual renal type was common. A most striking feature of the majority of the dropsical cases was the rapidity with which it subsided, although in any large series of cases some were seen of the type so familiar in civil hospitals where the dropsy was refractory to treatment and persisted. This rapid subsidence of considerable anasarca was certainly a novel experience to most observers familiar with renal dropsy as seen in London hospitals. In many cases where the anasarca was considerable on admission it had disappeared within a fortnight, and in slighter cases its duration was only a few days. Uræmic manifestations in the form of epileptiform fits were not uncommon, and such fits might be repeated and of great severity; nevertheless, they were rarely fatal. Other uræmic phenomena were uncommon. Inflammatory complications were uncommon, and the mortality from the disease, at any rate during its early stages, was very low. In a considerable series of cases personally examined in 1915 it was as low as 0·4 per cent. In a larger series for the year 1916 it was 0·93 per cent., and in 1917, when, as mentioned above, the statistics included cases of secondary nephritis complicating acute respiratory affections, and where death was at any rate partly dependent upon the respiratory disease, the rate was as high as 1·32 per cent.

The clinical study of these cases should make us revise some of our conceptions of renal disease and would seem to suggest that the clinical picture of the malady as we usually see it in civil hospitals is really the picture of certain more severe and unfavourable cases. Cases quite similar to these were seen amongst the large numbers of cases seen in the army, but the broad fact remains that the great majority of cases of acute nephritis, even when dropsy was considerable, or when severe epileptiform fits occurred, not only cleared up, but cleared up very rapidly. The fact seems to be that service in the army compelled a man with nephritis to seek medical advice at an earlier stage than is the case in civil life or when the illness was only slight, and thus we had the opportunity of obtaining a more correct impression of the

features of the disease, besides that of seeing very large numbers of cases, amounting in some instances to several thousand. It would seem that this is really a more satisfactory explanation of such differences as were found than to assume that the disease was a special and peculiar one to the army.

ACUTE INFECTIVE POLYNEURITIS.

Amongst the rarer forms of disease seen in France there was a group of cases of generalised palsy of a peculiar type but with very constant and uniform features and similar in character to certain cases described by Osler under the term of acute febrile polyneuritis. Isolated cases were seen from time to time during the earlier periods of the war, but a more considerable number was seen in 1917 and a few in 1918.

Onset.

Two modes of onset may be recognised. In one there is a definite history of an illness, usually of a slight character, prior to the onset of the palsy; in the other the onset of the palsy is the first manifestation of the disease. It is probable that the first mode of onset should be regarded as the more typical.

Usually the initial illness is of a mild character and moderate pyrexia, headache, vomiting, pain in the back and along the spine, together with some pain in the limbs and possibly in the abdominal wall, are the leading symptoms. The headache may be severe, and in a small proportion of cases the severity of the headache, vomiting, and pain in the back are such as to resemble the early symptoms of cerebro-spinal fever. The pyrexia is of short duration, lasting two to four days and rising usually to 100° to 101° F. Exceptionally a temperature as high as 103° has been observed. All the symptoms subside rapidly and the patient apparently regains his former health, and thus such cases are often regarded as being due to influenza or to pyrexia of uncertain origin. A period of latency now occurs which may last for as long as six weeks from the date of the onset of the initial illness and then the palsy becomes manifest. In other cases this period of latency is much shorter, and this would seem to be more especially the case in those instances where the initial symptoms were so severe as to resemble those of cerebro-spinal fever.

The Palsy.

In the less severe cases the onset of the palsy is noticed only as a general weakness that increases more or less rapidly.

In the more severe cases the onset of the palsy is more dramatic; thus a man may suddenly fall down on parade or on the march, and in one case under observation at the time, the patient sat down to his midday meal apparently well and was unable to rise. Even when the onset is as sudden and marked as this there is not complete paraplegia and the patient can often stand and sometimes even walk with assistance.

Numbness and tingling in the extremities may precede or accompany the onset of palsy, and pain in the back, limbs, and body may also occur at this time. Usually the palsy affects at first the legs and may be confined to them. The legs are affected as a whole, and no case has been seen where the palsy was limited to the distal segments of the limb nor where it was limited to one limb. In some cases where the patient only complains of weakness of the legs, examination reveals that the arms are also affected, but in many cases there is a distinct interval between the date of the onset of the leg palsy and that of involvement of the arms, and this interval may be as much as three days. A marked feature of the palsy is the greater involvement of the proximal portion of the limbs, so that the movements of the shoulder and hip muscles may be extremely weak at a time when the patient can move the fingers or toes freely. Similarly, the trunk movements are frequently affected, so that the patient is unable to raise himself in bed, sit up, and may be unable to turn in bed or even to raise his head from the pillow. When the trunk muscles are involved the patient's condition is necessarily very serious, and death may occur as a result of involvement of the muscles of respiration. Nevertheless, some cases recovered even when the helpless state produced by the palsy of the trunk muscles persisted for several weeks. Cases in which the palsy is widespread, involving trunk and limbs, but not severe in amount, are very apt to be overlooked and classed as functional or neurasthenic, or even suspected of malingering. Such cases may, however, really be very serious and even fatal, as not infrequently such palsy may increase rapidly and suddenly, and death has occurred in more than one case where 24 or 48 hours before no suspicion of the presence of grave organic disease had been entertained.

Facial paralysis is a most characteristic feature of the malady, and it is probably exceptional for it to be absent, although it may escape observation unless specially looked for.

This arises from the fact that the palsy is so frequently bilateral, and also it is rather a general weakness of all the face muscles than a complete palsy, hence there is frequently no asymmetry of the face. In a series of 20 cases with full records facial palsy is noted in 17 cases; in two no record is made, and in only one is there a definite note that facial palsy was not present at the time of examination. In five cases the facial palsy was unilateral when first observed, and in two of these it became bilateral; in 12 cases it was bilateral when the patient was first seen. Thus in 14 out of 17 cases the facial palsy was bilateral at some period of the illness. The onset of this palsy is often distinctly later than that of the limbs and trunk, and the interval may be as long as four days. The peculiar palsy described above as affecting the limbs, trunk, and face, and sometimes of an ascending type, is the most characteristic feature of the disease, but other palsies may occur. Thus difficulty in swallowing, especially of solids, may occur and in slight degree is not uncommon; palsy of the palate, however, is not common, and the nasal voice and difficulty in the swallowing of liquid such as is seen in diphtheric paralysis is uncommon. The larynx and tongue may be involved, and in one case the symptoms so produced were sufficiently marked for a diagnosis of labio-glossolaryngeal paralysis to have been made prior to the admission of the patient to hospital. Paralysis affecting the oculomotor nerves must be rare, as the only nerve affected in a series of over 30 cases was the sixth nerve, and this only in one case. No instance of palsy of the third or fourth nerve was seen, and thus ptosis was never observed.

Pain, numbness and tingling, anæsthesia and analgesia are usually present. The sensory loss is usually incomplete, relative rather than absolute, and affecting especially the distal segments of the limbs; its distribution may be of the glove or stocking type. Remissions in the extent of the sensory loss may occur, and the boundary line separating on a limb the normal area from that in which sensation is impaired may vary in position in one and the same case on different days.

Reflexes, Sphincters, and Cerebral Functions.

The tendon reflexes are absent in fully established cases, but in the early stages the knee-jerks may still be present at a time when the weakness of the legs is obvious; and in cases of the ascending type the ankle-jerks may be lost at a period when the knee-jerks are still present, although these also are lost later. The plantar reflex is usually lost, but the abdominal and cremasteric reflexes may be retained where the involvement of the trunk is not very marked. When the trunk is more involved the abdominal reflexes are lost. The pupil reflexes and the palatal reflex are not affected.

Sphincters are not usually affected, and even in the most severe and fatal cases the functions of micturition and defæcation may remain normal to the end. Defæcation may be rendered difficult owing to the weakness of the abdominal muscles, and in the early stages of the palsy there may be slight temporary retention of urine, requiring, perhaps, the use of the catheter once or twice. No case requiring continuous catheterisation was observed.

No case with stupor, delirium, or convulsions was observed, and consciousness was always retained even in fatal cases right up to the moment of death; and it was not uncommon for death to be sudden. In one case the patient was certainly inclined to sleep unduly, but he could always be easily roused, and then answered all questions quickly and intelligently. In one case there was some loss of taste and some slight impairment of vision, and examination revealed the presence of a central scotoma. Tachycardia may be a prominent feature and was sometimes the cause of serious errors of diagnosis, as the case was apt to be regarded as one of D.A.H. with neurasthenia. I know of two cases at least where death occurred suddenly in such cases. The urine may contain a small quantity of albumin and the blood shows the presence of moderate leucocytosis; the cerebro-spinal fluid is clear, limpid, and free from cells.

The mortality of the disease is high—8 deaths in a series of 30 cases personally observed. Half the deaths occurred within a week of the onset of the palsy and only one death after the eleventh day. In half of the fatal cases death was due to pulmonary complications; in the remaining cases death was more sudden and, although possibly dependent upon respiratory failure, it was not accompanied with gross pulmonary lesions.

In the cases where recovery took place the improvement in the palsy was slow and gradual, and a period as long as six months may be necessary for the patient to regain his usual health. The palsy is not followed by muscular wasting.

Remarks.

Such is a short summary of the clinical picture presented by acute infective polyneuritis. It would seem that the disease is a very definite clinical entity, although both on clinical grounds and from the results of the study of the morbid anatomy it is probable that it is not a neuritis but really a diffuse affection of the nervous system affecting both nerve cells and nerve fibres in the spinal cord, spinal ganglia, peripheral nerves, and to a slight degree the cerebral cortex. It probably has affinities both to poliomyelitis and to encephalitic lethargica, and possibly to other varieties of encephalitis; but one of the most remarkable features of the campaign is that although a fair number of cases of this disease was seen, poliomyelitis was very rare, and I saw no case of encephalitis lethargica until the spring of 1919.

DIURNAL VARIATIONS IN THE HÆMOGLOBIN CONTENT OF THE BLOOD.

BY GEORGES DREYER, C.B.E., M.A., M.D.,

FELLOW OF LINCOLN COLLEGE; PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF OXFORD;

H. C. BAZETT, O.B.E., M.C., M.A., D.M.,

FELLOW OF MAGDALEN COLLEGE; WELCH LECTURER IN CLINICAL PHYSIOLOGY, OXFORD;

AND

H. F. PIERCE, M.A.,

LATE MAJOR, AMERICAN MEDICAL AIR SERVICE.

(From the Department of Pathology, University of Oxford.)

THE necessity of paying due attention to daily variations in arriving at figures for the normal hæmoglobin content of the blood, a knowledge absolutely essential for the investigation of the blood under physiological and pathological conditions, has already been emphasised by one of us (G. D., 1919). In the same publication it was also pointed out how important it is to examine the person's blood at the time of the day when the smallest daily variations are exhibited—e.g., late afternoon—in order to arrive at a true estimate of normality (cf. Douglas, J. S. C., 1913).

On searching in the literature one is at once struck by the fact that the normal diurnal variations in the hæmoglobin percentage have hardly received any attention. In the paper by Douglas, Haldane, Henderson, and Schneider (1913) the subject is definitely considered and some actual figures are given. These workers record observations made four or five times during the working day, and they noticed in some cases the existence of definite differences. They seem, however, not to have laid any great stress on these changes with any constancy. Indirectly the subject has been approached in the remarkably careful and long series of observations of Lloyd Jones (1887) on the diurnal changes in the specific gravity of the blood. This author pointed out the existence of definite daily variations of the specific gravity, and found usually the highest specific gravity about 9 to 10 A.M., and the lowest between 6 and 7 P.M. In view of our own experiments there seems no doubt that these changes in specific gravity are to a great extent caused by differences in the hæmoglobin content, and it is interesting to note that the times of the day when he finds his highest and lowest specific gravities coincide closely with those where we find the highest and lowest hæmoglobin content.

While what we call normal daily variations of the hæmoglobin percentage have thus been left unconsidered, as of no consequence, a number of observers have investigated the changes in the hæmoglobin or red-cell content caused by exercise (Tornow, 1895; Willebrand, 1903; Hawk, 1904; and Boothby and Berry,

1915), fluid intake (Haldane and Priestley, 1916), the position of the body (Jørgensen, 1917), and so forth. Changes in position are stated to have no effect on the red-cell content, though a marked one on the number of white corpuscles, but most observers have found that violent exercise results in a concentration of the blood. It seems, however, hardly possible to form an accurate opinion of the actual changes taking place unless the diurnal variations are duly considered. In fact, some findings in the literature regarding changes in the hæmoglobin percentage seem to be most naturally explained as due to these diurnal variations. The subject here dealt with has been under investigation for several years in connexion with various researches by G. D. and his co-workers, though the only hitherto published figures are those contained in the paper by one of us (H. C. B., 1919), in which one curve was given for comparison with pathological cases.

Method Employed.

The technique used has been developed by one of us (G. D.), and has been used in the Department of Pathology at Oxford for all work dealing with the blood and hæmoglobin for the last 10 years. As no accurate description has so far been published we shall give shortly the details of the procedure. Its advantage is accuracy combined with entire absence of knowledge of the results while readings are being taken, thus entirely excluding personal bias.

Measuring pipettes.—The pipettes used are capillary pipettes drawn from glass tubing of about 6 mm. diameter. It is drawn out to form a capillary tube of such proportions that a length of about 15 cm. corresponds to a volume of 0.1 c.cm. The end of the pipette is out off sharply and squarely, and it is then graduated by means of mercury measured out from an accurately standardised 0.1 c.cm. pipette. The 0.1 c.cm. of mercury is thus used to graduate a large number of pipettes, which are thrown away after the blood has been measured. For taking the quantity of saline required for the dilution of the blood a 20 c.cm. pipette is employed, in which each cubic centimetre is graduated in 1/10ths.

The blood sample.—If the sample be taken from a finger it is absolutely essential that the capillary circulation should be free and normal, and not restricted as the result of cold or congestion, which produce readings above those obtained from venous samples (cf., Gibson, 1909). No squeezing should be allowed, and the blood should drop freely and have a natural bright colour. Only when this is done is it possible with any degree of certainty to obtain identical results when capillary blood is compared with blood drawn directly from a vein. Five or six drops are now collected into a freshly paraffined watch-glass and the dilution made immediately. While drawing up the blood into the capillary pipette it is necessary to agitate the watch-glass gently and continuously to prevent sedimentation of red cells, which takes place very quickly, and if this point is disregarded very considerable error will be introduced, while otherwise dilutions made from the same drop will give exactly identical readings. In the case of human bloods a dilution of 1 in 200—e.g., 0.1 c.cm. of blood in 19.9 c.cm. of normal saline—is convenient, while in the case of goats and rabbits a dilution of 1 in 150 is preferable owing to their lower hæmoglobin content. Immediately after dilution the blood suspension is carefully mixed, and the tubes with diluted blood are then left in the cold store (or a cool place) and are not hæmolyzed until immediately before they are read. As the hæmolytic agent, dry saponin is added (about as much as can be taken up by the terminal millimetre of a penknife). The tubes are then gently rotated and left in a warm room, or preferably in a water-bath at about 30° C., for a few minutes until complete hæmolysis of the red cells has taken place. Before taking readings one should ascertain that the hæmoglobin solution is perfectly clear. The non-hæmolyzed diluted red cells can with safety be kept in the cold store at a few degrees centigrade for 24 to 48 hours without showing any change, while the hæmolyzed blood kept under the same conditions shows a definite drop in the hæmoglobin content within the same time.

The taking of the hæmoglobin readings.—For all readings a Duboscq colorimeter is used. To secure accuracy and comparable results from day to day it is absolutely necessary to secure an even illumination on the two halves of the fields. To ensure this, and at the same time to secure a greater delicacy of reading, it is to be recommended always to use a yellowish artificial light in a dark room. The light should be so shaded that only the reflecting mirror is exposed to the light rays. It is always necessary on each occasion to determine the actual difference in reading obtained by

filling both cups with the same hæmoglobin solution, and in the calculation of the experiments to allow for these differences. If these details are scrupulously observed it is possible to obtain readings where the mean deviation is not greater than 0.3 per cent., when different hæmoglobin solutions are being read against each other. When a series of hæmoglobins is being compared, one of the samples is poured into the one cup and the other samples are in succession read against it. In the dilution of blood recommended a height of 10 mm. on the vertical measuring scale will give a good colour intensity for allowing accurate comparison. If too weak or too strong a colour is used the accuracy of the readings suffers considerably.

To secure and maintain an unchangeable standard from day to day and year to year, one or more of the bloods are finally read against a standard glass of suitable colour, and in this case it is absolutely necessary to use artificial light rich in yellow rays to obtain a perfect match of colour quality.

The advantage of using a Duboscq colorimeter is that it leaves the observer in absolute ignorance of the numerical reading until he has finally matched the colour, and therefore eliminates the personal equation, a factor of the greatest importance where minute changes have to be ascertained.

Observations.

The observations recorded in this paper have been carried out on goats and men. In the case of goats all blood samples have been taken by introducing a hollow needle into the external jugular vein and collecting the blood in a paraffined watch-glass as described above. In the case of men the samples have been taken in some of the experiments entirely from an arm vein, using a fine needle and a dry syringe, and in others by puncture of the back of a finger near the root of the nail. In a few experiments samples have been taken by both methods as nearly as possible at the same time, and in no case where the circulation has been free and normal, as already stated, has any difference been observed.

To exclude as far as possible the effects of feeding and rest, &c., on the curves, these conditions have been varied in different experiments, with the result that similar curves have been obtained under very diverse conditions. In men the changes found in the course of a long experiment in which no rest was taken for over 30 hours correspond fairly closely with others obtained when the individual was kept entirely at rest in bed, though the exact times for the rise and fall of the curves seem to be somewhat shifted in one direction or the other by the varied conditions. In all cases the times are given in real time, and we do not think that the change from ordinary time to "summer time" has produced any definite shifting of the curve. Even in one surgical patient in bed with marked excursions of temperature the general shape of the curve conformed to the normal type.

These points are brought out clearly by the five curves reproduced, four on men and one on a goat.

Curves 1, 2, and 3 (Fig. 1) are from different individuals within the same period of 25 hours, all the samples being taken from the arm veins without congestion. Curve 4 (Fig. 2) is from the same individual as curve 3, the samples being capillary blood obtained on another occasion by pricking the fingers. In the case of curves 1, 2, and 3 the persons stayed up the whole of the night without sleep or rest owing to the pressure of work. In the case of curve 4 the subject had a long night in bed, got up late, and did no work during the day. Although woken up at hourly intervals during the night, he slept well between the times when the blood samples were taken.

The most striking feature about curves 1, 2, and 3 is that, though the excursions between the highest and lowest readings show considerable variations, the general configurations of the curves are very similar, and the times of rise and fall are approximately the same. Towards the end of the experiment on subject 2 four control determinations were done by taking also capillary blood samples from the finger, which are represented by the broken line on the curve. The almost perfect correspondence between the two series of samples is evident. As a further control on many occasions two samples of blood have been taken with as short an interval as possible between them, and identical readings have usually been obtained, while a divergence of more than 1 per cent. has been extremely rare. Experimental errors are therefore probably slight.

A comparison of curves 3 and 4 shows a general similarity in character for the same individual on different occasions, though the contour seems to have been somewhat shifted to

one side or the other; and it is also to be remarked that the absolute excursions to be noticed from the highest to the lowest readings are very much greater in curve 4 than in curve 3, reading as much as some 15 per cent. The subject whose changes are given in curve 2 was also examined over part of the time corresponding to the experiment reproduced

FIG. 1.—Curves 1, 2, and 3 are all from venous samples in men. Interrupted line at the end of curve 2 indicates control observations on capillary samples. All three individuals took their meals as indicated in the figure. Subject 2 was lying down from 12.36 to 12.56 A.M., when sample (a) was taken, sample (b) being taken at 12.59 after standing three minutes. The same subject lay down from 6.42 to 6.52 A.M. when sample (c) was taken, sample (d) being taken at 6.58 after standing six minutes.

in curve 4, and again the time relations of the rise and fall were very similar in the two subjects, who lived under the same conditions as regards meals, though considerably different as regards rest. Any shift in the curve was therefore apparently the same in the two individuals.

The curves reproduced in this paper are merely samples taken from a large series of observations made on a number of different individuals. In all of the curves reproduced for man the subjects were males.

From these curves it will be seen that the distance between the various highest and the various lowest points correspond

FIG. 2.—Curve 4. Capillary samples from subject 3 on another occasion.

approximately to some four to six hour intervals, and while usually the lowest readings are found somewhat near midnight the highest readings are obtained in the mornings between 8 and 10, or in evening about the same time. During the working day the lowest values occur in the early evening, and there is therefore a general agreement with the results of Lloyd Jones, who found the lowest specific gravity about that time.

In curve 5 (Fig. 3) is represented one series of observations on a female goat; this curve is only a single illustration of a number of observations made on different goats in connexion with other investigations carried out by two of us (G. D. and H. F. P.), which will be published later. In the goat the

same general configuration of curve is to be found as in the case of man; though the exact hours do not absolutely coincide they fall fairly close together. Again, here we trace four to six intervals between the various highest and the various lowest points. The excursions are very considerable, even showing as much as 30 per cent. increase from the lowest to the highest reading, and that the changes may take place very rapidly is shown by the fact that within two hours an increase of some 23 per cent. is found, followed by a similar decrease within the next two hours.

There is some evidence that the female sex exhibits greater daily variations than the male.

Discussion of Results.

From the curves published it must become evident that in any kind of research dealing with observations where blood changes caused by extraneous influences are studied, it is absolutely essential to give the greatest possible consideration to diurnal variations in the concentration of the blood as shown by changes in the hæmoglobin percentage. If this is not done it is hardly possible to draw true and correct conclusions as to the real nature of any variations found. It is not unlikely that in view of the marked diurnal changes normally taking place we may have to reconsider results already obtained in a number of observations dealing with the blood and circulation, and it is also probable that some of the phenomena that have hitherto been veiled in obscurity may be more readily understood.

At the present moment we are unable to offer any rational explanation of these diurnal variations, though

FIG. 3.—Curve 5. Jugular vein samples from a goat. Animal fed each day at 3.45 P.M. and allowed access to food and water the whole time of the experiment.

there is strong evidence that they are closely connected with variations in pulse-rate, blood pressure, rate and volume of respiration, and possibly with fluid absorption or kidney secretion, though it would be premature to attempt to express an opinion as to which is the primary factor in bringing about these changes. We do not consider that the suggestions put forward by one of us (H. C. B.) in the preliminary communication already quoted afford an adequate explanation of the facts in the light of this extensive series of observations.

In connexion with what we have put forward it is worth mentioning that changes produced by cold in the capillary circulation greatly resemble those found during shock by Cannon (1917), though his views regarding changes in colour index must be taken with some reservation until they have been confirmed by experiments with improved methods. It is also worthy of notice that some of the data for diurnal variations in the rate of kidney secretion given by Leathes (1919) show some similarities with the times when changes in the concentration of the blood occur, though any interdependence of the two remains unproved.

Conclusions.

1. The diurnal variations in hæmoglobin percentage met with in man and animals are very considerable and may even reach as much as 30 per cent., while 10 per cent. changes are of more or less common occurrence.

On an average the excursions seem to be more marked in individuals or animals with a low hæmoglobin content of the blood.

2. In attempting to establish the normal hæmoglobin content in a series of individuals it is essential to take the observations at a time of the day when the daily variations are found to be the smallest—i.e., late afternoon between 5 and 7 P.M.

3. In the study of any phenomena where alterations in the concentration of blood are concerned it is necessary to view them in the light of the marked normal diurnal variations that may occur.

RUPTURE OF CÆSAREAN SECTION SCAR IN SUBSEQUENT PREGNANCY OR LABOUR.*

BY EARDLEY HOLLAND, M.D. LOND.,
F.R.C.S. ENG., F.R.C.P. LOND.,

ASSISTANT OBSTETRIC PHYSICIAN TO THE LONDON HOSPITAL;
OBSTETRIC SURGEON TO THE CITY OF LONDON
MATERNITY HOSPITAL.

An obstetric surgeon has seldom to face an accident of pregnancy or labour more disturbing to his peace of mind than rupture of the scar of a former Cæsarean section. My interest in the subject has been excited by the following series of events in the obstetrical department of the London Hospital. In November last I operated on a patient almost moribund from the effects of rupture of the scar of a Cæsarean section performed in 1915; in February of this year I saw in the post mortem room a patient dead from abdominal sepsis consequent on rupture of the scar of a Cæsarean section I had myself performed in 1916, and in the years 1915 and 1916 three other of our Cæsarean section patients got rupture of their scars. The occurrence of five of these treacherous accidents in five years has made a very great impression on the minds of myself and my colleagues.

On inquiring into the subject I was impressed with the fact that we possessed very little information about rupture of the scar, either as to its causes, or, far more important, as to the frequency with which it occurred. At the outset I was struck by the wide divergence of opinion amongst the few with whom I talked or corresponded. On the one hand, I was told that rupture of the scar was more or less of a myth; on the other hand, I learned that certain outstanding surgeons—the Camerons of Glasgow, for example—were so afraid of ruptured scars that their invariable custom was to sterilise their patients

at the first operation. Further inquiry proved that rupture of the scar was no myth, but was a real menace; I heard of recent cases in London and elsewhere; about a hundred cases had already been reported in the obstetrical literature of Europe and America. Obviously the subject required investigation. It seemed, above all, imperative to find out what was the actual frequency, the real risk, of rupture. Quite apart from the importance of this information to obstetric surgeons, patients themselves might wish to know what sort of obstetric future they were likely to have after submitting themselves to Cæsarean section. It seemed all the more important to get exact information in view of the increasing frequency with which the operation is being performed; its modern indications form an ever-growing list. There is another point: many patients who nowadays have had Cæsarean section have nothing to prevent them, in the event of a future pregnancy, from delivering themselves by the natural passages—a very different thing from the days when pelvic contraction was almost the only indication, when a repeated operation was the only way of future delivery, and when scars were seldom strained by labour.

If, on inquiry, the risk of scar-rupture was revealed to be a negligible one, then we could, with clear consciences, go on advising and performing the operation according to its extended indications; but if the risk turned out to be an appreciable one, then we should be forced to seek safety either by limiting the indications or by contriving an operative technique which would give a more dependable scar.

I have divided my paper into three sections: (1) An account of five new cases. (2) A general discussion on the ætiology and anatomy of ruptured scars and an analysis of the literature. (3) The results of a follow-up inquiry into the subsequent obstetric history of a large number of Cæsarean section patients operated on between 1912 and 1918.

1. AN ACCOUNT OF FIVE NEW CASES.

The details of the five new cases, from the London Hospital, are as follows:—

CASE 1.—Cæsarean section, 17/4/14, by Dr. Russell Andrews. Primigravida, aged 22, with extreme contraction of the pelvic outlet. Entered hospital early in labour at term. Uterus opened by anterior median incision; sutured with two layers of chromic catgut, a deep buried one including whole thickness of the muscle and missing endometrium, and a continuous peritoneal suture. Living child, weight 6½ lb. Recovery good, temperature not above 99.4° F. during first four days, and afterwards not above normal.

Readmitted 13/8/15, with rupture of scar. No intervening pregnancy. Last menstrual period 11/11/14. Pain began suddenly on 13/8/15 at 2.30 A.M.; a continuous cramping pain which doubled her up made her vomit and faint. Admitted at 8 A.M., anæmic, pulse 120; was in continuous abdominal pain, uterus very tender and hard, abdominal muscles rigid, foetal heart not heard; no labour pains, no external hæmorrhage. Concealed accidental hæmorrhage diagnosed. Laparotomy by the late Dr. Drummond Maxwell. An ovoid rupture, 1½ inches long, was seen in upper part of uterine scar. Placental tissue protruded through the rupture, and blood was oozing from it; about 2 pints of blood in peritoneal cavity. The uterus, with the ovum in situ, was removed by subtotal hysterectomy, and patient made a good recovery.

CASE 2.—Primigravida, age 19, admitted 26/7/14 with eclampsia, in thirty-eighth week of pregnancy. Before admission had already had five convulsions; between 5 A.M. and 11.30 A.M. had convulsions every half hour; treated with morphia, venesection, and intravenous saline. After temporary improvement convulsions increased in severity and frequency. At 2.30 P.M. Cæsarean section by Mr. Gordon Luker; labour had already started. Uterus opened by anterior median incision. Recently dead 7½ lb. foetus delivered. Incision sutured with two layers of chromic catgut, deep and superficial. Convalescence febrile; temperature rose daily to 102° F. for first four days, for next seven it ranged between 100° and 103°. Patient was discharged well on 16/8/14; abdominal wound healed by primary union.

Readmitted 19/11/15 in state of collapse in eighth month of second pregnancy. Laparotomy by Dr. Drummond Maxwell; dead foetus and much blood in peritoneal cavity; rupture through scar of former Cæsarean section; placenta lay almost completely outside uterus, being still attached to one side of rent. Uterus removed by subtotal hysterectomy, but patient died shortly afterwards.

Description of the uterus: A uterus with a long, widely gaping rupture through anterior wall. Outside measurements of uterus: Length, 14.5 cm.; greatest width, 14 cm. Measurements of rupture: Length, 10.5 cm.; width at upper end, 7 cm.; at lower end, 5 cm. Thickness of uterine wall at edges of rupture, 2 cm. near the upper end, decreasing to 1.5 cm. near lower end. Continuous with the lower angle of the rupture is a linear thinned area in the uterine wall 2.5 cm. long; this is the unruptured part of the scar and is only 0.5 cm. thick. The edges of the uterine wall at the site of rupture are for the most part rounded and smooth. At first sight the impression is got that the whole thickness of the

* A paper read before the Obstetrical Section of the Royal Society of Medicine, May, 1920. Full table of cases of Cæsarean Section used in the collective investigation, as well as short abstracts of all reported cases of rupture of the scar, will be published in the Proceedings of the Royal Society of Medicine.

uterine wall had been torn through, but closer inspection shows that the decidua lining of the uterine cavity is continued up over these rounded edges and reaches in most places very close to the torn peritoneum. (See Fig. 1.) At the upper and lower ends of the ruptured area decidua and peritoneum almost meet. The irregularly torn peritoneal layer overhangs liberally the thick decidua-covered edges. (Fig. 2.) In the middle two-thirds, on both sides, is a well-defined subperitoneal hematoma stripping the peritoneum for some distance from the underlying uterine wall. Firmly adherent to the middle third of the whole thickness of the left edge of the ruptured area is a piece of placenta, covered by loosened peritoneum and a subperitoneal hematoma. (See Fig. 2.) On the opposite edge the decidua layer is absent and is replaced by a roughened area covered with broken laminae of clot; this

FIG. 1.—Drawing of section through upper third of uterus. Note—(1) Broad rounded edges of ununited muscle; (2) the decidua covers these edges and reaches almost to the peritoneum; (3) the narrow band of tissue between peritoneum and decidua on the right side, through which rupture has occurred; (4) the overhanging flap of wide thin scar area, consisting of little else than peritoneum.

FIG. 2.—Drawing through middle of uterus. Note, in addition to points in Fig. 1—(1) Insertion of a piece of placenta into left edge of ununited muscle edge; (2) subperitoneal hematoma; (3) the broad thin scar area has torn through at one edge and not along its middle.

evidently represents part of the placental site. There are the remains of many thick omental adhesions to the peritoneum over the ruptured area. These findings are to be interpreted as follows. (1) The real scar, through which the rupture occurred, is extremely thin, and consists of little more than stretched peritoneum with here and there a thin layer of fibrous tissue. In its original state, before rupture, no doubt this thin peritoneal scar was covered beneath with decidua. (2) The thick edges of the ruptured area are the ununited muscle wall of the uterus, covered with decidua, except where they enter into the placental site. (3) The placenta was inserted over the scar and into the thick ununited muscle edges. (4) Retroplacental hemorrhage probably occurred beneath the stretched scar before rupture occurred; in fact, retroplacental hemorrhage may have been the determining cause of rupture.

CASE 3.—Cæsarean section, 26/3/14, by Dr. Russell Andrews. Patient aged 28, with flat rickety pelvis. Former labours: (1) 1911, instrumental dead-birth; (2) 1912, instrumental live-birth. Last menstrual period, 14/8/13; admitted in thirty-second week of pregnancy, on 26/3/14, after 18 hours in labour; os uteri two-fifths dilated, membranes intact, transverse presentation; head found too large to enter pelvic brim, so Cæsarean section performed; uterus opened by usual anterior median incision; sutured with two layers of chromic catgut, a deep buried one including whole thickness of muscle and missing endometrium, and a continuous peritoneal suture. Child alive; weight, 5½ lb. Convalescence febrile, temperature rising daily for 13 days to 100° or 101° F.

Readmitted early in fourth labour on 16/3/16, thirty-two weeks pregnant. Labour pains began at 2.30 p.m. At 6 p.m. spontaneous rupture of the uterus, accompanied by collapse, pronounced anemia, cessation of labour pains, and distinctive feeling of fetus beneath abdominal wall. Immediate laparotomy; dead fetus, placenta, and much blood were in peritoneal cavity. Scar ruptured in entire length; uterus removed by subtotal hysterectomy. Next day patient got left hemiplegia, but ultimately made good recovery.

CASE 4.—Rickety flat pelvis. Preceding obstetrical history: 1. Instrumental labour at term; dead-birth. 2. Instrumental labour at term; child lived a few hours. 3. Instrumental labour at

term; dead-birth. In fourth labour at term patient admitted on 11/10/14, and Cæsarean section performed by the late Dr. Drummond Maxwell; anterior median incision, sutured with two layers, deep and superficial, of chromic catgut. Child alive, weight 6½ lb. Convalescence febrile; temperature rose to 102.8° F. on second day, and varied between 100° and 103° until seventh day, after which it gradually fell.

Readmitted in fifth labour, at term, in 1916. Head engaged in pelvic brim; forceps applied, and a healthy child of 7 lb. delivered. Puerperium febrile; temperature rose to 103° on fourth day, fell by lysis, and reached normal on ninth day.

Readmitted in sixth pregnancy with rupture of uterus on 8/8/19; last menstruated on 1/12/18. At 12 o'clock, midday, whilst sitting in a chair, suddenly got intense abdominal pain and fainted; her friends summoned assistance at 3 p.m. She was found in last stages of collapse, and was immediately transported to hospital. On arrival was profoundly anemic and collapsed; abdomen distended and extremely tender; fetus felt with remarkable distinctness, and what was surmised to be empty uterus was felt reaching to umbilicus. Immediate operation by Mr. Eardley Holland, under stavaine spinal anesthesia; dead fetus and much blood found free in peritoneal cavity. The placenta was almost completely separated, and lying just outside a large gaping rent in anterior wall of uterus, a very small part being still attached near the left edge of the rupture. After removing fetus and placenta attention was turned to the uterus, which was rigidly contracted and anemic, with a long, widely gaping rupture occupying almost whole length of anterior wall. The rupture looked like a clean tear, except at its upper and lower ends, where it had extended laterally to a slight extent. Its edges were thick and smooth, giving the false impression that the rupture had occurred through the entire thickness of the uterine wall. Projecting from the thick edge of one side was a ragged leaf of thickened peritoneum, about 1 cm. wide; this was in reality the stretched scar, and it had ruptured, not along its middle, but along its junction with the opposite thick edge. There had been a complete failure of muscular union, and the ununited muscle formed the two thick edges. The rupture was rapidly closed with a single layer of interrupted sutures of No. 3 silk, placed about ½ cm. apart, and including whole thickness of uterine wall except endometrium. Patient made an excellent recovery. For first week evening temperature rose to 100°, but there was no other trouble.

CASE 5.—Cæsarean section, 26/2/17, by Mr. Eardley Holland. Primigravida, age 20, admitted with eclampsia in thirty-sixth week of pregnancy. Had three convulsions before admission, was comatose, and urine, on boiling, was solid with albumin; cervix intact, no labour pains, fetal heart heard. Cæsarean section under stavaine spinal anesthesia; uterus opened by anterior median incision, fetus dead, placenta posterior. Incision closed with No. 3 interrupted silk sutures, placed about ½ cm. apart, including whole thickness of uterine wall except endometrium; this layer was covered with a continuous peritoneal suture. Convalescence febrile; temperature ranged between 100° and 102.6° F. for first seven days, lochia offensive; abdominal wound healed by primary union.

During second pregnancy was a regular attendant at antenatal department. Last period 28/5/19; urine never contained albumin, and health excellent. Was admitted again on 17/1/20, with severe puerperal sepsis following premature confinement. Only an imperfect history could be obtained; labour was completed in a few hours on 11/1/20; placenta retained, and was removed manually, with difficulty, two hours after birth of child, which lived only a few hours. The following day she got abdominal pain and dyspnoea, and was sent into hospital. On admission into septicæmia ward on 17/1/20 was extremely ill; temperature 104°, pulse 120, abdomen rigid and tender, constant diarrhoea. She was considered to have puerperal septicæmia, but blood cultures taken on different occasions were sterile. Perineum completely ruptured to rectum. For a fortnight she held her ground and even improved slightly in her general condition. Abdominal section was considered and rejected. The discharge from her uterus became more and more offensive, and was ultimately fecal in character. She died on 16/2/20.

Post-mortem examination notes: General purulent peritonitis, with localised abscesses. Fibrous peritoneal adhesions at fundus of uterus, between bladder, uterus, and small and large intestines. Pus tracking up right and left sides of abdominal cavity. Localised subdiaphragmatic abscess in antero-superior surface of right lobe of liver. Perforation 1 cm. in diameter in wall of small intestine, 240 cm. below duodeno-jejunal flexure. Dense fibrous peritoneal adhesions with pus pockets between lower coils of small intestine and uterus. Rounded perforation 3 × 2 cm. on anterior wall of fundus of uterus. Dirty-green diptheroid inflammation of endometrium. Dilatation with purulent content in Fallopian tubes. The pelvic viscera were removed en masse, and showed the following details. Uterine cavity 7 × 4 × 4 cm. The rupture measured 3 × 2 cm., with rounded and smooth edges; the right edge was 1.5 cm. thick, and the left 0.5 cm. The scar had ruptured in its lower two-thirds; the unruptured part, which could be seen and felt as a thin furrow on the inner surface of the anterior wall, was 1.8 cm. long; remains of many old firm adhesions over anterior surface and fundus of uterus, one particularly broad and firm one covering unruptured part of scar. Left half of uterovesical pouch of peritoneum obliterated by dense adhesions between bladder and uterus; to right of mid-line it was occupied by an abscess cavity with fecal contents. This abscess communicated with the already-mentioned tear or perforation in the small intestine and with the uterine cavity, through the rupture. Thus, there had been a utero-intestinal fistula. Whether the intestine was injured at the time the rupture occurred, or whether the perforation arose subsequently, cannot be said for certain; I favour the former view.

A point of special interest in this case is whether the scar ruptured spontaneously during labour, or whether it was ruptured during the difficult manual removal of the placenta. In the light of other reported cases I am inclined to think it ruptured during labour, and that the retention of the placenta, as well as the difficulty of its removal, was due to its partial escape into the peritoneal cavity.

2. ETIOLOGY AND PATHOLOGY OF RUPTURED SCARS: REVIEW OF THE LITERATURE.

I have found accounts of 92 cases, reported in sufficient detail to make them worth collective study, and have made a short abstract of the essential facts of each case. I have omitted a few cases to which I found references, but of which I could neither get at the original report nor find reliable abstracts. It is obvious, too, that many cases have never been published at all; speakers in discussions before societies on the subject of ruptured scars often refer to such cases, personal or otherwise. Up to a point, references to cases were not hard to find, and I am indebted to other writers who have published collections of cases, especially to L. Singer (1909), Albert Wyss (1912), Palmer Findley (1916), and E. Schroeder (1916).

The classical operation dates from 1882, when Säger and others published their suture methods. I need hardly state that I have not included cases of ruptured scar following the operation of pre-suture days; one-half of the minority who survived this operation got a ruptured scar in the unfortunate event of a future pregnancy. The first case in my list, Koblanck's, occurred in 1891, and more than two-thirds have been reported since 1910, coinciding with the period when the indications for Cæsarean section began to be extended. Unfortunately, all cases are not found reported in full detail; but amongst the sum of the cases the data are in sufficient number to indicate the chief factors favouring rupture of the scar. I have isolated the essential points of these 92 reported cases and of my own five in the following summary, so that the extent to which each one occurs can be conveniently noted and its individual importance estimated.

Summarised Analysis of Reported Cases.

Parity.—Rupture occurred in the second pregnancy in 54 cases, the third in 19, the fourth in 10, the fifth in 6, the sixth in 3, the eighth in 1; number of preceding pregnancies not mentioned in 4.

Indications for Cæsarean section.—Contracted pelvis in 64 cases; eclampsia in 12; nephritis, albuminuria of pregnancy, fibromyoma of uterus, hamatoma of vagina and vulva, sacral tumour, stricture of cervix, vaginal varices, shoulder presentation, concealed accidental hæmorrhage in 1 each; dermoid cyst of ovary in 2; indication not mentioned in 10.

Cæsarean section incision.—Anterior median in 54 cases, posterior median in 1, transverse fundal in 28, anterior median and transverse fundal (repeated operation) in 1, cervical in 1, site of incision not mentioned in 12.

Relation of incision to placental site at Cæsarean section.—Incision through placental site in 10 cases, not through placental site in 6, placental site not mentioned in 81.

Suture material.—Catgut in 41 cases, silk (often with continuous catgut for the peritoneum) in 12, reindeer tendon in 1, suture material not mentioned in 43 cases.

Fever or sepsis during recovery from Cæsarean section.—Recovery febrile, or abdominal or uterine infection, in 51 cases; recovery stated to be afebrile in 15 cases; no details mentioned in 31.

Interval between Cæsarean section and rupture.—Less than one year in 2 cases, one year in 12, two years in 25, three years in 21, four years in 13, five years in 3, six years in 3, more than six years (including one of 11 and one of 12) in 4; interval not stated in 14 cases.

Number of Cæsarean sections preceding rupture.—One in 88 cases, two in 6, three in 2, number not mentioned in 1 case.

Number of labours intervening between Cæsarean section and rupture.—None in 85 cases, one in 8, number not stated in 4 cases.

Period of pregnancy at which rupture occurred.—At term in 47 cases, near term in 6, 8½ months in one, 8 months in 10, 7½ months in 1, 7 months in 8, 4 months and again at 7 months in 1, 38 weeks in 3, 37 weeks in 2, 36 weeks in 4, 32 weeks in 2, in early pregnancy in 1, at 11 months (post-mature) in 1, period not stated in 10.

Whether rupture occurred during labour or before the onset of labour.—In labour in 19 cases; in labour, early in first stage, in 29; during pregnancy, before the onset of labour, in 36; no details given in 13.

Relation of placenta to scar at time of rupture.—Placenta implanted over scar in 34 cases, placenta not implanted over scar in 17, placental site not mentioned in 46.

Accidental factors likely to have been exciting cause of rupture.—None mentioned in 80 cases, hydramnios in 2, twins and hydramnios in 1, version in 2, induction and version in 2, accidental hæmorrhage in 1, an accident in 1, difficult breech labour in 1, post-mature fetus in 1, fetus excessively large in 1, placenta prævia (hydrostatic bag) in 1, pituitrin in 1, pituitrin and obstructed breech labour in 1, manual removal of placenta in 1, long labour with contracted pelvis in 1.

Extent of rupture.—Rupture of entire or almost entire length of scar in 67 cases; rupture of small portion only of scar in 22; extent not mentioned in 8.

Treatment of rupture.—Hysterectomy (subtotal) in 56 cases; vaginal hysterectomy in 2; suture, sometimes with excision of

edges, in 26; drainage in 2; treatment not stated in 1; death before operative treatment in 10.

Result to mother.—Lived in 66 cases, died in 28, not mentioned in 3.

Result to child.—Dead in 69 cases, lived in 21, not mentioned in 7.

The Anatomy of the Uterine Scar.

(A) *Perfectly healed scars.*—Perfect healing of the uterine incision may result in complete muscular regeneration, leaving no trace of scar tissue except on the peritoneal surface.

Whitridge Williams has studied the cicatrix in 10 uteri, removed by Cæsarean hysterectomy, which had been subjected to Cæsarean section upon one or more previous occasions. In 8 of his specimens (one of which had been subjected to two, and another to three, previous Cæsarean sections) it was difficult to find the old cicatrix by examination with the naked eye; the only indication of its existence was the presence of slight vertical depressions upon the external and internal surfaces of the uterus. Microscopical examination revealed the entire absence of scar tissue in the uterine wall, and showed the muscle fibres extending across the site of the old incision as if it had never existed. It is interesting to note that the convalescence from the previous operations had been uncomplicated.

In another specimen deep furrows existed on the external and internal surfaces of the uterus, the two being separated by a band of tissue 3 mm. thick, in contrast to the adjacent uterine walls, which measured 2.5 cm. in thickness. The external furrow was covered with peritoneum and the internal was lined with typical decidua; the intervening tissue was normal muscle, showing no trace of scar tissue, and differing from the normal only by its thinness. The history of this patient was that the convalescence had been stormy.

(B) *Thin scars.*—Light is thrown on the causes and anatomy of ruptured scars by studying scars that are thin, for it is only thin scars that are likely to rupture. A thin scar becomes progressively stretched and thinned during pregnancy owing to the increasing distension of the uterus.

Thinning of the scar, as found at a repeated Cæsarean section or in a uterus removed for some reason from a patient who has formerly had a Cæsarean section, is not at all uncommon; every obstetric surgeon of experience has encountered it. Harrar, at the New York Lying-in Hospital, found that in 50 instances of the repeated operation in 42 the old scar was either not found at all or, if found, was solid, in 4 there was marked attenuation, in 2 there was partial rupture at the location of the old scar, and in 2 there was complete rupture. Van Leuwen collected all cases of repeated operation reported in literature down to 1903, and found thin scars reported in 20 out of 117 cases. These figures probably represent cases of extreme thinning only. A moderate degree of thinning or extreme thinning of a small portion of the scar is, in my experience, much more common than this if looked for by palpating the whole length of the scar, after the uterus has been emptied, between a finger within and a finger without the uterus. By various writers these wide, thin scar areas, as found at repeated operations, have been described as, "as thin as paper," "only 1 to 2 mm. thick," and have sometimes been mistaken for the bulging amnion herniated through the scar. Sometimes a subperitoneal hæmatoma has been observed—an indication of imminent rupture.

There are, of course, varying degrees of thinning of the scar. Sometimes it is extreme, sometimes moderate; sometimes the entire length of the scar is affected, sometimes only a part. The only case I have found recorded in which the thin scar consisted of normal muscle is that of Whitridge Williams, to which I have already referred. In all others it was composed of scar tissue, often with a varying proportion of muscle fibres scattered through it. In my own second case the unruptured part of the scar consists almost entirely of scar tissue, but muscle fibres, singly or in groups, are scattered through it, and have even grown right across its whole width. In cases of extreme thinning the attenuated scar area consists merely of peritoneum in contact with decidua, with a few intervening strands of fibrous tissue. These attenuated peritoneo-decidual scars are just the ones liable to rupture during pregnancy or labour from a rise of intra-uterine pressure. The point of greatest importance about these scars is that the uterine muscle has completely failed to unite; the sutures employed to close the incision either slough out or cut out, and the muscle surfaces retract and become widely separated. The peritoneum, on the contrary, holds firm. The retracted muscle surfaces later become smooth and rounded and in course of time covered by a layer of endometrium, which in a subsequent pregnancy is converted into decidua. The endometrium grows also across the line of the scar beneath the peritoneum and

covers the inner surface of the gap. Further thinning of this peritoneo-decidual scar is the natural sequence of the distension of the uterus during pregnancy.

The analogy between such a scar and a defective abdominal scar is irresistible; the one consists of peritoneum and decidua, and the other of peritoneum and skin; in both the muscle is wanting. In some cases even peritoneal union has been demonstrated to have failed in parts of the scar, and the gaps have been plugged by adherent omentum or even bowel. Excellent histological studies of thin scars have been published by Couvelaire, Offermann, Spalding, and others.

(C) *Ruptured scars*.—There is no doubt that when the scar has ruptured it has nearly always been one of the thin scars described in the foregoing section. The peritoneo-decidual scar has gradually become converted into a widely stretched area during the progressive uterine distension. When this thin area ruptures it has usually been noticed that the line of rupture does not occur along its middle, but at the sides, near the thick part of the uterine wall. A thick or even a moderately thick scar, whether composed of fibrous or muscular tissue or both, does not rupture except under extreme provocation, such as obstructed labour.

The appearance of a ruptured scar, after the uterine contents have escaped and retraction has occurred, is deceptive and has, in the earlier observed cases, led to wrong descriptions and tortuous explanations. The deceptive feature is the thickness of the edges of the ruptured area. These edges, as already pointed out, consist of the ununited muscle surface covered with decidua. After the uterus is emptied and retracted these muscle edges become equal in thickness to the rest of the uterine wall. Furthermore, these thick edges, since chorion or placenta has been separated from them, are either found oozing blood or covered with pieces of blood clot. In fact, their appearance is almost exactly as if the whole thickness of the uterine wall had been newly torn through, whereas in reality it is only the stretched deciduo-peritoneal area that has given way. The true state of affairs is illustrated in Figs. 1 and 2, where the decidua can be followed from the uterine cavity over the ununited muscle edges almost up to the ruptured peritoneal coat. In my own fourth case, where I sutured the rupture, I believed I was suturing thick, recently ruptured surfaces; it is only in the light of the experience from my second case and of cases reported in the literature that I now realise I sutured together the old ununited muscle surfaces.

Liability of Uterine Incision to Yield Shortly After Operation.

It is not often that Cæsaean section cases come to post mortem, and it is even rarer for a case to be reopened for hæmorrhage or sepsis. In such cases it is surprising how often there has been observed a yielding of the incision from the loosening or cutting through of the sutures.

Wyss has made a small collection of these cases. Sheffzek reports two post mortems after Cæsaean section in which the catgut sutures had become completely unknotted. Boissard reports the case of a patient who died from sepsis on the fifth day; four of the interrupted catgut sutures had become untied and the incision gaped widely; there was intraperitoneal hæmorrhage, and the uterine cavity was filled with blood clot. Cristalli reports a case where, because of severe and persistent hæmorrhage following Cæsaean section, the abdomen was reopened; a gap was found in the uterine incision, which had been sutured with silk. One is led to believe that this accident may sometimes happen in cases that recover; they would not necessarily pass through a stormy convalescence, for such an accident, without sepsis or with only local sepsis, should not produce much disturbance. The partially or completely gaping scar would quickly be sealed or plugged by omentum. It is quite probable that the firm adhesion of omentum to the old scar, so commonly found in cases of repeated Cæsaean section or subsequent rupture, may represent the same protective plug.

Utero-abdominal Fistula.

This is not a great rarity, following infection of the uterine and abdominal wounds, and may persist for many months: the uterine scar in such cases is bound to be extremely defective and liable to rupture in subsequent pregnancy. Amongst the reported cases of ruptured scar, utero-abdominal fistulæ had followed the Cæsaean section in five.

If accompanying the fistula the uterine scar is completely adherent to the abdominal wall, subsequent rupture may be entirely extraperitoneal. An interesting example of

this is recorded by Noble (not placed amongst the list of ruptured scars). A utero-abdominal fistula persisted after the first Cæsaean section; another pregnancy soon followed and the liquor amni escaped through the fistula in the thirty-third week. The second Cæsaean section was performed by enlarging the fistulous opening; the uterine scar was found completely adherent to the abdominal wall, and the operation was entirely extraperitoneal.

The Site of the Uterine Incision and Subsequent Rupture.

On referring to the summary of reported cases it will be noted that, in the 85 cases where the site of incision was stated, the anterior median incision was employed 55 times, the transverse fundal 28 times, and the cervical only once. There is no doubt that the transverse fundal incision, introduced by Fritch in 1897, is specially liable to rupture. The number of ruptures after this incision, compared with the number after the anterior median, is relatively very high, considering how late it was introduced, and how relatively few must be the number of Cæsaean sections in which this incision was employed. A point which theoretically favours rupture of transverse fundal scars is that most of the muscle bundles are cut at right angles, and the incision therefore tends to gape widely, favouring imperfect union.

The incision that at present holds the best record for immunity from rupture is the cervical (by this I mean the transperitoneal or extraperitoneal cervical operations, of which, as is well known, there are many varieties). All the same, before this incision is lauded because of its apparent immunity from rupture it must be remembered that very few cervical Cæsaean sections have, up to now, been performed, compared to the thousands of classical and transverse fundal Cæsaean sections; it still has to stand the test of time.

The cervical incision was first employed by Frank in 1906. It was at once pointed out by the theorists that the cervical scar would be specially prone to rupture; it lay in that part of the uterus most subjected to stretching during labour, and, being placed nearer the contaminated area (i.e., the vulvo-vaginal tract), would therefore be more liable to infection. These fears have not been fulfilled; only one case of rupture has been reported, by Wolff in 1914, and only a small number of thin cervical scars have been observed, in spite of the fact that many cases of subsequent pregnancy have occurred. There seem to be excellent reasons for the sound healing of cervical scars. Rest is an essential to good union of divided muscles; a state of rest or immobility is impossible in the body of the puerperal uterus, where contractions and relaxations are constantly tending to disturb the apposed surfaces and draw the healing muscle fibres apart. All operators are aware of the great lateral tension on the sutures and of the tendency of the incision to gape during a strong contraction. On the other hand, the cervical incision is situated in a quiet part of the uterus which does not undergo contractions and relaxations. In Frank's original operation he incised the cervix transversely; this has now been generally replaced by a longitudinal incision. The stretching and rupture of the transverse scar would seem more likely because its line lies at right angles to the direction of the chief pull of the uterine muscle fibres; whereas the longitudinal scar lies in the line of the pull, and its edges have scarcely any tendency to be drawn apart.

Influence of Implantation of the Placenta over the Scar.

The relation of the placenta to the scar at the time of rupture was noted in 51 out of the 97 cases; in 34 cases it was implanted over the scar, and in 17 it was not. From this it may be assumed that the implantation of the placenta has at all events a share in predisposing the scar to rupture, but far too great importance has in the past been attached to this point. That the placenta cannot be the direct cause of rupture is obvious enough, for, on the one hand, the placenta is very often not over the scar in cases of rupture, and, on the other, in cases of repeated Cæsaean section it is often found over the scar without any harmful effect.

The idea that implantation of the placenta over the scar was the cause of rupture came very early into the field. It was known that rupture of the pregnant tube was caused by the eroding action of the villi, and that in certain cases of placenta prævia the lower uterine segment was appreciably weakened and more liable to traumatic rupture. An analogy between these two and scar rupture was tempting; but there is no histological evidence to show that chorionic villi invade scar tissue any more than they do normal uterine

tissue. It has also been suggested that when at the original Cæsaean section the incision is over the placental site perfect healing is interfered with; there is no histological evidence for this. Amongst the 97 cases of ruptured scar the relation of the incision to the placental site at the original Cæsaean section is only mentioned in 16 cases, in 10 of which the incision was over the placental site. Nothing can be inferred from these figures; it must be remembered that when the operator encounters the placenta in his incision he may state the fact in his records, but that he is much less likely to state the negative fact.

I believe the reason why implantation of the placenta over a thin scar increases its liability to rupture is the occurrence of retroplacental hæmorrhage. The first step towards this is a gradual yielding and widening of the scar area; there follows a very gradual, and probably very slight, separation of the placenta over and adjacent to the scar area. The mechanism of this separation is comparable to the separation of a placenta prævia from the lower uterine segment when the cervix begins to dilate. Hæmorrhage between the scar area and the placenta will bring about a sudden rise of pressure sufficient to precipitate rupture. In my own Case 2 there was beneath the peritoneal scar area a well-defined subperitoneal hæmatoma, which had extended laterally, stripping the peritoneum off the uterine wall; I do not think this occurred entirely after the event. In a case of ruptured scar reported by Wing there was a well-defined blood clot on the maternal surface of the placenta, and there can hardly be any doubt that hæmorrhage between the scar area and the placenta was the direct cause of the rupture.

Effect of Sepsis on the Healing of the Uterine Wound.

Of all the causes of imperfectly healed scars sepsis is by far the most important. Reference to the summary shows that fever or sepsis during recovery from the Cæsaean section was noted in 51 out of 66 cases; in only 15 of the 66 was the recovery afebrile. It is obvious that infection and suppuration of the uterine incision must of necessity be followed by imperfect healing.

If the septic process be severe the uterine tissues included between the sutures will undergo necrosis; the sutures will cut out, the muscular walls will retract, and the end result will be a scar which consists of little more than peritoneum with a protective layer of omentum or other adhesions. Even if the sutures do not cut out, the wound will have to pass through a stage of granulation tissue, and will result in a broad, fibrous scar. If silk be employed, the suppurative process will continue until the silk sutures have come away; cases have been recorded in which silk sutures were found in the uterine discharges. In the two cases recorded by Wyss, in one silk stitch sinuses persisted for many months; and in the other, after a persistence of stitch sinuses, the linen thread sutures were removed from the interior of the uterus by curetting. If catgut be employed, its absorption will be hastened by sepsis. The point will be raised that in 15 cases of rupture there was no evidence of sepsis in that the convalescence was afebrile. But infection of the uterine wound may occur without rise of temperature, or with only a very slight one; for example, few will deny that the presence of extensive adhesions to the scar at a subsequent operation is evidence of sepsis during the healing process, and there must be many operators who have found these adhesions when the temperature chart of the original Cæsaean section did not betray sepsis. For example, at a second operation I found such extensive adhesions of the great omentum to the abdominal wall and to the uterine incision, accompanied by such a number of enormously distended blood-vessels, that I had to evert the uterus and incise its posterior wall; palpation of the old scar showed that it was extremely thin in places, and formed a series of deep pits on the inner surface of the uterus. After the first operation the temperature had been charted every two hours during the first five days; on the second day the highest record was 99.6° F., on the third 99°, on the fourth 98°, on the fifth 98.4°. During the following days the only records above normal were 99.2° on the ninth day, 99.8° on the eleventh, and 99.6° on the fourteenth. The abdominal wound healed by primary union, and the patient made an exceptionally smooth convalescence. Silk was employed to suture the uterus. Here there had clearly been infection of the uterine wound, and yet the temperature chart did not betray it. The point is, that although the temperature chart may be a smooth one, infection of the uterine wound may occur sufficient to impair healing. I believe that the operation of Cæsaean section can never be guaranteed as a surgically clean one, for there is a large wound in a mucous cavity in direct communication with, and within a short distance of, a contaminated area (the vulvo-vaginal tract). It is sufficiently well known that hæmolytic streptococci have frequently been found in the normal puerperium, not only in the vagina, but also in the apparently healthy

uterus. I have been surprised by the large number of Cæsaean section cases in which the recovery was febrile; in the London Hospital and City of London Maternity Hospital series of 84 cases recovery was afebrile in only 38, or 45 per cent. (trivial rise of temperature in first 48 hours of course not counted).

A study of the type of convalescence from a Cæsaean section is of the utmost importance in arriving at a decision as to the management of future pregnancies.

If the convalescence has been febrile and there has been other evidence of sepsis the scar is probably thin and there is risk of rupture. If, on the other hand, convalescence has been afebrile the chance of rupture is a very small one, but it is quite plain that there is no absolute guarantee against rupture, since an appreciable number of cases of rupture have been reported even after an afebrile convalescence. On the other hand, it can be shown that patients whose convalescence has been accompanied by even considerable fever can successfully deliver themselves on a future occasion by the natural passages.

Suture Material and Method of Suture.

In all the cases under review except one the entire thickness of the uterine wall was sutured either by introducing buried layers, or by using deep sutures which passed through the whole thickness of the uterine wall except the endometrium. There is no need to dwell upon this point, as it may be taken for granted that all modern operators take good care to unite the whole thickness of the uterine wall.

Great controversy has waged about the best suture material for closing the uterine incision. On looking at the table it will be noted that, out of the 53 cases in which the suture material used for the deep sutures is mentioned, catgut was employed in 41 and silk in 12; in most of the cases in which silk was used there was also a superficial peritoneal suture burying the knots of the deep layer. It would be false reasoning to conclude from these figures that rupture is more liable to occur after catgut than after silk. Before it is justifiable to come to such a conclusion it would be necessary to know the relative frequency with which silk and catgut were employed. In Great Britain, up to the year 1910, Dr. Amand Routh's book tells us (p. 23) that, of the 81 operators who sent him particulars, 41 used silk for the deep sutures, 27 catgut, 8 silkworm gut, and 4 linen thread. Since the date of this inquiry, amongst those surgeons who have sent me particulars of their cases for the period under investigation (1912-1918) the use of catgut is far more customary than that of silk. (See Table I.) From reading modern text-books and monographs by American and German authors it is apparent that catgut is almost universally used in those countries; in France silk is still preferred. There seems to be no doubt that catgut has been in the past, and still is, far more commonly employed than silk. It is not justifiable therefore to conclude from the figures relating to the use of catgut and silk respectively, in cases of ruptured scar, that catgut is more blameworthy than silk.

The suture material can, of course, only be of importance during the process of healing, and so long as a slowly absorbable preparation of catgut, such as chromic, is used, capable of resisting absorption for at least three weeks, there can be no objection to its use so long as the wound is healing aseptically. A point that has been emphasised is that in the involuting uterus the intracellular enzyme activity is considerably raised, and that therefore a protein material, such as catgut, would be absorbed more quickly than in other tissues; this point is a sound one, and is sufficient reason for not employing plain catgut, which is quickly absorbable. If the uterine incision becomes infected the process of healing is, of course, considerably delayed, and the absorption of catgut hastened; for this reason I think catgut has serious disadvantages. In the case of an infected wound, whose muscular edges are constantly tending to be drawn apart by the retractile power of the muscle, it is important that the edges should be kept in apposition for as long as possible. Here catgut fails, and a less absorbable material is far preferable. Since it is, in my opinion, impossible to guarantee aseptic healing of the uterine incision, I believe that catgut should be avoided. (See also Part 3 for the conclusion arrived at as the result of the collective investigation.)

Considering now the two types of non-absorbable suture, we have to consider silk or linen thread and silkworm gut.

Theoretically, silkworm gut is far the more preferable; it is well known that if infection occurs silk sutures encourage the process of suppuration, which goes on almost indefinitely, and seldom ceases before the sutures have come away.

naturally or have been removed. Silk in an infected wound is an irritant and an inveterate harbourer of bacteria. On the other hand, silkworm gut is an inert material in the presence of bacteria, and has little or no influence in prolonging the suppurating process. My own opinion is strongly in favour of the use of silkworm gut for the deep uterine sutures, firstly, because it is a non-absorbable material and will hold the sides of the uterine incision in place for an indefinite period of time, unless, of course, it cuts out owing to an extensive necrosis of the tissues; secondly, because it is an inert material in the presence of bacteria. It is interesting to note that no case of ruptured scar has been reported in which silkworm gut was used; it would be wrong, of course, from this to jump to a too obvious conclusion, for silkworm gut has been relatively very seldom employed.

Another point I consider of great importance in suturing is to wait for complete retraction before inserting the sutures; if the wound is sutured before retraction is complete and the muscular walls are thin the result is bound to be a scar thinner than the rest of the uterine wall, for the sutures fail to include layers of muscle fibres which during complete retraction would have slid inwards and become rearranged, adding to the thickness of the sides of the incision.

Accidental Factors in Causation of Rupture.

Any circumstance in pregnancy or labour which is likely to strain the scar to an exceptional degree may precipitate rupture in a case in which, under ordinary circumstances, the scar, though a weak one, might have remained intact.

Such circumstances in pregnancy are the over-distension of the uterus by hydramnios, excessive size of the fetus or twins, a large retroplacental hæmorrhage, or the introduction of a hydrostatic bag; in labour, prolonged or obstructed labour, internal version, or the use of pituitary extract. It will be noted that such accidental factors are recorded in only 17 of the 97 cases. A study of these cases points the moral that patients who bear Cæsaean section scars should not be allowed long labours, and that the employment of version, bags, or ecbolic drugs is to be avoided.

Some Clinical Points.

Parity, interval between the Cæsaean section and rupture, number of Cæsaean sections preceding rupture, treatment, and result to mother and child require no further comment here. The bare facts are sufficient, and will be found in the summary of cases. Other points deserve closer consideration.

Labours intervening between Cæsaean section and rupture.—In eight cases one delivery by the natural passages occurred between the two events. Why did the uterus stand the stress of one pregnancy and labour only to yield to it in the next? We naturally turn to inquire whether any additional stress had been put on the scar beyond that of the normal state. In four of these we find unusual circumstances: in one the labour lasted 20 hours and the pelvis was contracted; in one the placenta was implanted over the scar; in one delivery was by internal version; and in one labour was induced by a hydrostatic bag for toxæmia of pregnancy. In the other four there was no abnormality of pregnancy or labour; it is unwise, therefore, to indulge in any false sense of security merely because a patient has already delivered herself by the natural passages.

Period of pregnancy at which rupture occurred.—In 70 out of the 87 cases in which the period is stated the scar ruptured at full term or within a month of it. In a case reported by Hermann either the scar had ruptured at a very early period of pregnancy or, what is much more likely, the original Cæsaean section incision had always remained open from imperfect healing and was sealed by adhesions only; the ovum had developed partly in the uterus and partly in the abdominal cavity. The fetus lay in an intraperitoneal gestation sac—a case of secondary abdominal pregnancy. In one case (Richter) a partial rupture occurred in the fourth month, which was completed at the seventh. Of the cases where rupture occurred in the seventh month (see summary) only two was there any explanation for such early rupture: in one a bag was inserted for placenta prævia, and in the other the placenta was implanted over the scar. Circumstances which should favour early rupture are implantation of the placenta over the scar and retroplacental hæmorrhage, hydramnios, and operative manipulation; also excessive thinness of the scar, especially where there are gaps in the line of the scar merely closed by omental adhesions.

Moment of rupture, during pregnancy or during labour.—It will be observed from the summary that in the 84 cases in which this point is stated rupture occurred during labour in

48 and before the onset of labour in 36. Of the former rupture occurred early in the first stage in 29. This aspect of the subject is plain enough; a scar is much more strained during uterine contractions than during the quiescent period of pregnancy, and if labour be allowed to continue for a long time, especially if obstructed, the scar is subjected to an unwarrantable strain. A point worth bearing in mind is that for many patients who go into labour subsequently to a Cæsaean section the labour is for all intents and purposes a primiparous one; a patient who has had labours previous to the operation is less likely to strain her scar and get a rupture than a patient whose operation was done when she was a primigravida. Other circumstances which obviously favour rupture during pregnancy are over-distension of the uterus and implantation of the placenta over the scar with retroplacental hæmorrhage; only a few examples of such will be found amongst the 36 reported cases, and it must be assumed that thin scars often yield under the influence of the normal intra-uterine pressure. The possibility of rupture of the scar during pregnancy and as early as the seventh month is a very sinister feature of the accident. It makes it difficult for us, however forewarned by our knowledge of the risk run by the patient, to protect her completely from the consequences; we cannot very well keep her under close observation in a hospital or nursing home from the seventh month onwards, ready to operate at the first sign or symptom.

Cases with absence of, or with very slight, symptoms.—All are familiar with the usual signs of rupture of the uterus: sudden pain, collapse, signs of intraperitoneal bleeding, cessation of labour pains, and the distinctive feeling of the fetus and retracted uterus. The point about these cases of ruptured scar is that the signs and symptoms are often extremely slight and are not seldom absent altogether. The explanation is not far to seek; instead of the whole thickness of the uterine wall being torn through, only a membranous and avascular scar has yielded; instead of sudden rupture being determined by powerful and prolonged uterine action in an exhausted patient, the rupture often occurs quietly and gradually during pregnancy or the early stage of labour. The membranous scar yields at one point, a small bag of membrane bulges through, and the patient goes into labour, as it were, through a gradually yielding scar until the ovum is born into the peritoneal cavity. The severity of the symptoms is naturally dependent on the position of the placenta. If the placenta is implanted over the scar, hæmorrhage is likely to be very severe; if the placenta is well away from the scar, it separates and is expelled into the peritoneal cavity with very little more hæmorrhage than occurs after a normal third stage of labour. In cases where the rupture is partial and the ovum is still in the uterus acute symptoms are obviously not to be expected. In some cases a partial rupture, sometimes only a small perforation, has been quite unexpectedly discovered at a repeated Cæsaean section. If the placenta is over the scar, even a small perforation may be accompanied by considerable intraperitoneal hæmorrhage. Apart from the type of rupture—i.e., whether complete or a mere perforation—in 6 of the reported cases symptoms were entirely absent and in 14 they were extremely slight. Three cases of complete rupture, accompanied by escape of the fetus and placenta into the peritoneal cavity, with extremely slight and misleading symptoms, may be quoted as examples. In Munro Kerr's case the absence of symptoms caused a mistake in diagnosis; there was no collapse, only a slight alteration in pulse-rate, and slight abdominal pain and tenderness. In Breitstein's case the only symptoms were slight pain and a feeling of weight in the lower abdomen, worse on standing. In Novak's case there was no intraperitoneal hæmorrhage or shock; there was diffuse abdominal pain for a few days, after which the patient was comparatively comfortable, walking about with little inconvenience.

The Frequency of Rupture.

Upon this all-important point we possess, up to the present, no reliable information.

Harrar, reviewing the records of 50 repeated operations at the New York Lying-in Hospital, found two partial and two complete ruptures of the scar. Spalding states that of 40 patients who had Cæsaean sections in his clinic or in his private practice, only one patient, to his knowledge, had had spontaneous labour later. This patient, after one spontaneous labour, got rupture of the scar in her next pregnancy. Jolly refers to his case as the third during the last 30 years at Olshausen's Clinic. Asa B. Davis states he had had only 9 ruptured scars out of the 360 Cæsaean sections he had done (? personally). These figures, interesting as they may be, throw no light whatever on the actual frequency of ruptured Cæsaean section scars.

The only way of arriving at the truth is to get the subsequent obstetric history of a large number of Cæsaean section patients, and this forms the subject of Part 3.

3. RESULTS OF A FOLLOW-UP INQUIRY.

This section deals with the results of a follow-up inquiry into the subsequent history of a series of Cæsaean section patients operated on between 1912 and 1918. I was, of course, especially concerned about the five cases of rupture at the London Hospital, and was anxious to find out what proportion these cases bore to the number of our Cæsaean section patients who subsequently became pregnant. This meant a follow-up inquiry. The difficulty was to decide how far back to go in selecting a year for the beginning of the period of inquiry. It was useless to go too far back, as there would be a small chance of getting hold of patients who had their operation at too remote a date in a class that changes its abode so often. I decided on the period 1912 to 1918. The results of this inquiry would give the frequency of ruptures at the London Hospital, but it would not give a reliable figure for the percentage of ruptures in general, for the London Hospital cases were only a small sample selected from the mass of cases throughout the country. Further, it was a special sample, in that it contained, without a shadow of doubt, a high proportion of cases of ruptured scar. A much larger and more mixed sample was necessary. So, to begin with, I decided to add to the London Hospital cases the cases from the City of London Maternity Hospital, taken over the same period; in the latter hospital there had been no case of ruptured scar.

These combined figures work out as follows:—

Total number of Cæsaean sections (excluding fatal cases, sterilised cases, and cases of repeated Cæsaean section where the first operation was performed prior to 1912) ...	112
Number of patients who were followed up ...	84
Number in whom no subsequent pregnancy occurred ...	49
Number who subsequently became pregnant ...	35

Results of pregnancies:

Delivery by natural passages 10	Pregnant now ...	4
Repeated Cæsaean section 15	Rupture of the scar ...	5
Abortion ...	5	

These depressing figures show that 5 pregnancies out of 30 (i.e., after deducting abortions and patients in the early months of pregnancy), or 16 per cent., resulted in rupture of the scar, and that there were half as many ruptures as deliveries by the natural passages. They further show an unexpected degree of sterility following the operation.

Leaving now the main line of argument for a moment, I will refer to an objection which can be raised against these figures; it is that the follow-up failed in 25 per cent. of the patients, and that some of these patients may have become pregnant and may have got ruptured scars, or have had spontaneous deliveries, or what not. My own conviction is that these patients either did not become pregnant or had early abortions. If they had been expecting confinements they would almost certainly have sought the advice of their hospital, except in the few cases where they had left London. If all patients had been successfully followed up the only result would have been the recording of a still higher percentage of sterility.

To return to the main argument, it was essential to take a much larger sample of cases than that taken from the London and City of London Maternity Hospitals if the figures were to be statistically reliable. As it seemed of such immense importance to get at the truth, I decided to try and get the results of Cæsaean sections done throughout the country during the same period. I therefore wrote to many obstetric surgeons in active hospital practice, asking them to collaborate with me in a collective investigation. This investigation has been a complete success, in that we are in possession of the subsequent obstetric history of 1103 cases of Cæsaean section (including the London Hospital and City of London Maternity Hospital cases already referred to) performed between the years 1912 and 1918 inclusive.

Result of the Collective Investigation.

In Table I. are displayed the number of cases and their sources, together with the number followed up, the number that subsequently became pregnant, and the mode of termination of the pregnancies. The

suture material, as used in the total number of Cæsaean sections, is also shown.

The table may be summarised as follows:—

Total number of Cæsaean section patients (excluding fatal and sterilised cases, and cases of repeated Cæsaean section where the first operation was performed prior to 1912) ...	1605
Number followed up ...	1103
Number in whom no subsequent pregnancy occurred ...	616
Number who subsequently became pregnant ...	487

Results of pregnancies:

Delivered by natural passages ...	78	Abortion now ...	47
Repeated Cæsaean section ...	352	Pregnant now ...	86
		Rupture of scar ...	18

The discrepancy between the number of pregnancies and the number of patients who became pregnant is, of course, accounted for by the fact that some patients became pregnant more than once.

A good many interesting points could be worked out from the lists of cases I have had sent me: for example, the sterility rate that follows Cæsaean section. But here I intend only to work out two—viz., the frequency of rupture and the suture material. (The publication in full of the lists of cases will give anyone who so wishes the opportunity of working out other points, or for checking my own results.)

The Frequency of Rupture.

Out of the 487 patients who became pregnant 18 (or 3.6 per cent.) got ruptured scars. This figure does not represent the true frequency of rupture; it is necessary to know the frequency of rupture amongst the pregnancies that went to, or near to, term and were therefore liable to get ruptured scars. Adding together the repeated Cæsaean sections, the deliveries by the natural passages and the ruptured scars, we find they come to 448. The true frequency of rupture is 18 in 448, or 4 per cent. It is also interesting to note that the proportion of ruptured scars to successful deliveries by the natural passages is 18 to 74, or 1 to 4.3.

The Suture Material.

Out of 1089 Cæsaean sections in which the suture material is noted (see Table I.), in 731 catgut was used, in 288 silk, and in 70 silkworm gut. The frequency with

which these suture materials was used in general works out at 67 per cent. catgut, 26 per cent. silk, and 6 per cent. silkworm gut (incidence of catgut to silk equals 1 in $2\frac{1}{2}$).

In the cases of ruptured scar catgut was used in 15 cases, silk in two, and in one case there is no record of the suture material. In no case was silkworm gut used. The frequency with which the suture materials was used in cases of ruptured scar works out at 88 per cent. catgut, 12 per cent. silk, 0 per cent. silkworm gut (incidence of catgut to silk equals 1 to 7). The number of silkworm gut cases is, of course, too small to draw conclusions from. It is thus apparent that the incidence of catgut to silk in cases of ruptured scar is nearly three times its incidence in Cæsarean section in general. From this it might be inferred that scars are nearly three times as liable to rupture after the use of catgut as after the use of silk.

But to this conclusion a reasonable objection may be raised. It may be urged that perhaps very few cases of pregnancy followed the use of silk compared to the number that followed catgut.

For example, if only 10 or 20 cases of advanced pregnancy or labour occurred amongst the silk cases silk would come badly out of the ordeal, with two ruptures to its credit. This objection can quite easily be met and overcome. It is necessary to find out the proportion of ruptures to advanced pregnancies amongst the silk cases and compare it to the proportion of ruptures to advanced pregnancies amongst the catgut cases. This information is set out in Table II.:

TABLE II.

	Repeated Cæs. sect.	Delivery by nat. pass.	Rupture.	Total.
Catgut	237	49	15	301
Silk... ..	72	19	2	93
Silkworm gut	15	6	0	21

This shows that 15 ruptures occurred in 301 cases of advanced pregnancy (i.e., repeated Cæsarean section, plus delivery by the natural passages plus rupture) after the use of catgut, a proportion of 1 in 20; and that two ruptures occurred in 91 cases after the use of silk, a proportion of 1 in 46.5. That is about 2 per cent. of the silk cases, and 5 per cent. of the catgut cases were followed by rupture in subsequent pregnancy.

The liability to rupture after catgut is, therefore, nearly two and a half times the liability after silk. Put in another way, if silk had been used instead of catgut in the above 301 catgut cases, and ruptures had occurred in the same proportion as for the silk cases, there would have been only six ruptures instead of 15, and the total number of ruptures for all cases would have been reduced from 17 to 8.

From the facts revealed by these figures there can be no doubt that catgut is a dangerous suture material for Cæsarean section, and henceforth should be discarded.

CONCLUSIONS.

(1) The frequency of rupture of the Cæsarean section scar in subsequent pregnancy or labour (abortions excluded) is 4 per cent.

(2) The cause of ruptured scar is imperfect healing, leading to a thin scar in which muscular union has failed, and which consists of little more than peritoneum and decidua with a varying amount of intervening fibrous tissue.

(3) All thin scars stretch during pregnancy; rupture of a thin scar may be determined solely by the intra-uterine tension of normal pregnancy or by the uterine contractions of normal labour; or it may be favoured by various accidental factors, of which the chief is insertion of the placenta over the scar, with partial separation of the placenta, and retroplacental hæmorrhage.

(4) Other accidental factors are over-distension of the uterus, prolonged or obstructed labour, operative interference, such as internal version, the insertion of hydrostatic bags, and the administration of such drugs as pituitrin.

(5) In the reported cases rupture occurred almost as often during pregnancy as during labour (in proportion of three to four); and many cases have been reported as early as the seventh month of pregnancy.

(6) The chief cause of imperfect healing is infection of the uterine wound; other causes are imperfect methods of suture and the employment of unsuitable suture material.

(7) As regards the suture material, catgut should not be used, for the liability to rupture after catgut is two and a half times the liability after silk. For theoretical reasons silkworm gut is the most suitable material.

(8) As regards the incision, the scar of the transverse fundal incision is especially liable to rupture. Only one case has so far been reported of rupture of the scar of the cervical incision.

I wish to tender my most sincere thanks to my fellow obstetric surgeons in the British Isles who have so generously responded to my call for a collective investigation. The collection of these lists has occasioned an immense amount of careful work to those who have undertaken the task. It is the utmost gratification to me, as I am sure it is to them, that our work has met with success and has revealed so many outstanding facts about a subject of such great importance to us all.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF

TRAUMATIC DISPLACEMENT OF LUMBAR VERTEBRA:

RECTIFICATION AFTER TWELVE YEARS.

By C. WESTMAN, M.R.C.S. ENG.,

MEDICAL OFFICER IN CHARGE OF THE MASSAGE AND ELECTRO-THERAPEUTIC DEPARTMENT, GREAT NORTHERN CENTRAL HOSPITAL.

THE following case indicates the value of X ray examination in cases of obscure backaches before resort to manipulative treatment. Treatment can then be rationally directed to the lesion at fault, and valuable time saved.

History.—H.E., 28 years old, fell down eight or nine stone steps during Easter, 1908. She was able to get up unassisted and to walk, but felt great pain in the lower lumbar and sacral region, particularly in attempting to stoop or lift anything. She stayed in bed for 36 hours and was unable to turn herself, or even half sit up. She then returned to her nursing duties, but although the back pain was bearable it was persistent and only gradually began to settle down. The stiffness and pain—which have been more or less present ever since—was particularly pronounced during 1909, when it made itself felt in several acute attacks of a severe nature. Treatment by heat and massage only gave temporary relief. The condition became worse in the latter half of 1918, when the trouble seemed to spread

to the upper part of the back. At the end of that year the neck and shoulders also began to be stiff and painful—chiefly on the right side. There was aching when sitting down, even for a short time, and difficulty in standing upright. The general condition naturally suffered by the continuous aching, and frequent spells of sick leave were needed. The back, however, did not improve, but went from bad to worse during the end of 1919.

Examination, Feb., 1920.—There were great tenderness and irritability of the lumbar muscles, chiefly on the right side. In standing the left shoulder was held higher than the right, the whole body tending to lean towards this side. The hips were level. When stooping, which was accompanied by great pain and which could not be done as far as the horizontal plane, there was marked deviation of the trunk to the right in a manner which is never seen in cases of lateral curvature of the spine, not even of the severest type. This deviation was also present when lying down. In fact, the greatest difficulty was encountered in trying to put the patient in a straight position. When standing, side-bending of the trunk to the right was comparatively easy, but almost impossible to the left. There were also stiffness and pain in the cervical region.

X ray examination.—A X ray plate of the back (Fig. 1), which had been taken by the recommendation of Dr. H. C. Cameron on Jan. 1st, showed a local bend of the spinal column between the third and fourth lumbar vertebrae in a manner which I think can only be explained by forcible locking between the articular processes of these vertebrae, which presumably happened at the accident 12 years ago. The lower articular process of the third vertebra has a relation to the fourth articular process, which could scarcely by itself be brought about in a normal side-bending motion.

The malposition of the third lumbar vertebra, in addition to an associated irritation and contraction of the erector spinae muscle, sufficiently explained both the general stiffness and the lateral deviation of the back.

Treatment.—Manipulative treatment began on Jan. 15th in the form of mobilising movements, partly general for the spine and partly directly aiming at freeing the abnormal adherence between the third and fourth lumbar vertebrae. In addition, general back massage was given for easing the pain and rendering the muscles more supple. The result was complete correction of the faulty position, confirmed by an X ray plate taken on March 3rd, which shows a completely straight spine. The correction was probably

was instructed to bend herself over to the right side as far as she could. The figure confirms the fact that the lumbar spine permits of a considerable amount of side flexion, and it is interesting to note how evenly distributed the bending is along all the lumbar vertebrae without any exaggerated approximation between any special two of them. Mr. J. M. Redding—to whom I am indebted for the X ray plates—stated in his report

FIG. 2.—Radiogram of the lumbar spine in a normal subject (female, aged 35) lying prone, with the maximum active lateral bend. The inclination between L. 2, L. 3, L. 4, and L. 5 is 7°, 8° and 6° respectively.

of Jan. 7th that "there are fairly well-marked osteo-arthritis changes in both knees and fairly advanced osteo-arthritis of lumbar spine at junction of fourth and fifth vertebrae." It would be interesting to know if this condition is a separate one, or whether it is secondary and dependent upon the malposition of the vertebrae, giving rise to trophic changes from pressure irritation of nerves.

Patient now states there is less pain, apart from movement. She can now stand and lie straight, rests better in bed, and appetite and sleep improved.

I wish to express my gratitude to Dr. Cameron for permission to publish this case.

A CASE OF IDIOPATHIC ATONY OF THE BLADDER.

BY S. M. VASSALO, M.D.,

UGANDA MEDICAL SERVICE.

THE following case of atony of the bladder is of interest, not so much from the clinical as from the pathological point of view.

W., native male, aged about 50. Was admitted into hospital on Feb. 12th. Patient was in great pain and complained that he had not passed water for a fortnight. On examination there was a marked median abdominal swelling reaching to the umbilicus, and a certain amount of incontinence shown by dribbling. The temperature was normal, pulse good, respiration slightly increased. A history of gonorrhoea was obtained, but the patient gave conflicting accounts of the date at which he suffered from this disease. Naturally obstruction, due to stricture, was first thought of, but this was soon excluded as a No. 9 E. catheter was passed without the slightest difficulty. At the first sitting 2½ pints of urine were withdrawn; there was pus in the urine, which was very foul and offensive.

Treatment.—The following routine treatment was adopted. The bladder was washed out twice daily, after the urine had been

FIG. 1.—Radiogram of the lumbar spine of H. E. before rectification. The upper arrow indicates the interval between L. 3 and L. 4, the inclination here (obtained by measuring the angle between the lines, joining the tips of the transverse processes) being 65°, and that between L. 4 and L. 5 practically nil. The lower arrow indicates the unusual relation of the articular processes.

gradual at first, judging from the steady improvement in executing the stooping exercises, which were done with less and less deviation from Jan. 19th. On Feb. 20th, however, while passively stretching the spine, a distinct "snap" was heard by both patient and operator, the former also having a "sensation of something slipping into a different position" in the lumbar region; this, in all probability, meant that the vertebrae were finally unlocked. After this occurrence there was a sensation of relief and greater freedom of movement in the back, and soon after the bending-down movement from a standing position with straight knees could be done to normal range, with fingers easily touching the floor and without any lateral deviation. The nocturnal rest, which had previously been much disturbed—probably from difficulty in getting into a comfortable position—improved greatly.

Comment.

To verify the fact that the original malposition of the third lumbar vertebra was traumatic and not merely postural, and in view of the fact that other arthritic changes in the vertebral articulations were present, an X ray plate was taken (Fig. 2) of a normal spine, in a position of side flexion. The subject, a female, aged 35, lying prone,

withdrawn, with a weak solution of sodii bicarb. and ac. boric, a certain amount being left in after each washing. Internally patient was given urotropin and a mixture of liq. ext. ergot and tr. nucis vomice, the object of the latter being to increase the contractility of the bladder. The general toilette of the body was also attended to. On the 16th the urine was much clearer, but there was no improvement in the tone of the bladder; the dribbling had, however, ceased, which showed that the sphincter vesicæ was acting better. There was no improvement for another four or five days, until on the 21st the patient passed about six ounces of urine. The flow was, of course, very weak, and the act of micturition on this occasion occupied about ten minutes. From that day onwards improvement, though gradual, was very steady, and now (March 3rd) patient passes urine quite easily, and there is no more cystitis. Unfortunately, he refuses to stay in hospital any longer, and so it is rather difficult to say whether the improvement is temporary or permanent. He feels greatly relieved, and has promised to return should there be any sign of recurrence.

Remarks.

The series of events in this case does not appear quite clear. The cystitis and residual urine are easily understood, but not the sudden distension. The symptoms in this case were identical with those occurring in spinal cases, of which there were no signs whatever; moreover, in a nervous case one could not expect such marked improvement in such a short time, the bladder functioning normally, as far as can be seen, in less than three weeks. Syphilis can also safely be excluded. There was a history of gonorrhœa, but even granted that the gonococcus had migrated via the posterior urethra to the bladder, it would not produce such a train of symptoms, and the gonococcus has no special affinity for the nerves of the bladder or of any other organ. I might also add that, though frequent smears were taken from a purulent discharge at the anterior urethra, no gonococci were ever found; this, I think, will allow us to rule out gonorrhœa as the cause of the trouble.

The only literature in my possession with any allusion to this form of atony of the bladder is Thomson Walker's "Genito-Urinary Surgery," where he says that in all his cases the power of voluntary micturition remained, although greatly impaired. Further on he gives as the cause of such cases "a lesion in the lowest reflex centres of the bladder—namely, the hypogastric and hæmorrhoidal plexus of the sympathetic, ... but why such a lesion should remain confined to the bladder centre in all these cases is difficult of explanation" (1914, p. 537). For lack of a better explanation one has to accept this one just given, but I would be grateful to know if anybody who has had similar cases has arrived at a more satisfying conclusion.

A NOTE ON A

LIVING FOREIGN BODY IN THE EAR.

By ARTHUR WOOD, M.B., B.CH. CAMB., &C.

RECENTLY a man came to see me in urgent haste, saying that he had an "animal" in his ear. Three-quarters of an hour previously he had been walking near a wall which was well warmed in the sun, when suddenly something flew into his ear from the wall. He had been syringed with water and had had oil poured in, but it had not killed the creature, for it was still making a loud and most unpleasant noise. With the aid of a syringe I easily removed a moth, which was about the size of a silver-Y; the remnants of its wings were very dark. Naturally these were frayed and almost scaleless, but it was still alive, though it had been subjected to so many and various douches. I have extracted a dead but unsuspected earwig, the patient not having the slightest idea when it got in, but I have never seen a moth, nor would I have thought it possible for the insect to get in before the man had caught it by the tail.

Rugby.

DONATIONS AND BEQUESTS.—Miss E. A. Maynard has by her will bequeathed £5000 to the Ranyard Mission, which has 85 district nurses working in different parts of London, and a similar sum to the Church of England Zenana Missionary Society.—The late Mr. W. Lewin, of Wellingborough, left £21 to his medical attendant as a token of appreciative regard.

Medical Societies.

CONGRESSES OF PHYSIOLOGY.

PARIS: INTER-ALLIED CONGRESS OF PHYSIOLOGY.

THE Inter-Allied Congress of Physiology—for the present, at least, no longer an International Congress—met at Paris from July 16th–20th. CHARLES RICHET, the learned and eloquent Professor of Physiology in the Faculty of Medicine was the appropriate President, having been appointed by the International Congress at its last meeting, held before the War in Groningen.

Presidential Address.

In his address of welcome to the members the PRESIDENT said that this was the first meeting of the Congress on French soil, to which he cordially welcomed them. He referred in elegant and appropriate terms to the memory of those workers in physiology and allied sciences whose deaths had occurred since the last meeting of the Congress. The President's message, addressed more especially to his younger listeners, was "Cherchez à connaître les choses, l'utilité viendra plus tard; c'est d'abord la connaissance qui importe." In illustration of this advice he referred to the fruitful, yet at the time seemingly unpractical, investigations of Claude Bernard on the sugar-forming function of the liver. In the same connexion he spoke of his own researches on anaphylaxis—a word coined by himself—a condition which has found abundant application in practical medicine and therapeutics. His first investigations were carried out with Portier on board the yacht of Prince Albert of Monaco when on a scientific voyage to South America, the experiments being made on birds with the poisons obtained from certain sea anemones living in tropical waters. The President concluded by the reflection that there were three great problems confronting physiologists at the present time. First the whole question of nutrition and alimentation, including that of vitamins. This "infamous war" had shown clearly that our conceptions of the minimal alimentary ration were erroneous, and that the rôle of fats in nutrition, of which we previously had but little knowledge, was of profound importance. The mysterious nutriment known as vitamins called into serious question the physiological value of our methods of cooking. The second great problem was the physiology of the brain. For almost 40 years this subject had scarcely made any progress. Our ignorance of ideation, memory, psychic reflexes, and their localisation was almost complete. The third question was both vast and obscure—heredity, and quite pertinently the speaker asked why physiologists left this problem to botanists, zoologists, and agriculturists, and commended the study of the lower animals and microbes in this regard. By prosecuting research with ingenuity and ardour surprises and discoveries would be found both numerous and happy.

Other Communications.

Numerous interesting communications followed.

M. DOYON, of Lyon, gave a demonstration on Blood Coagulation, bearing especially on antithrombin and nucleinate of soda. The substance in the blood which prevents coagulation in "peptone-plasma" seems to be of nuclear origin, and owes its activity to specific phosphorus compounds. From plasma—from a dog injected with peptone—by heating and dilute acetic acid, there is obtained a precipitate of coagulated proteins—amongst them a nucleo-protein containing 3 per cent. of phosphorus, which is capable of preventing coagulation of the blood *in vitro*. It seems to be derived from the nuclei of cellular organs; in fact, from all the tissues of the dog can be obtained an anti-coagulant substance identical in action with that present in dog's peptone-plasma. Blood shed directly into a solution of nucleinate of soda remains fluid, and in a few hours undergoes marked hæmolysis. The

addition of calcic chloride rapidly determines coagulation. The soda salts of all the nucleic acids possess the same anticoagulative property and oppose the action of the fibrin ferment. Nucleate of soda prevents the action of yeast on sugar and that of the liver on glycogen.

P. HEGER, of Brussels, described hypertrophy of the right heart as an adaptation to altitudes. A relative hypertrophy of the right heart has been observed in the ptarmigan living in the high Alps, and careful measurements of races of cattle acclimatised to altitudes confirm this. The cause of this relative hypertrophy is to be sought in the fact that diminution of the atmospheric pressure causes a persistent pulmonary hyperæmia, leading to overfilling of the right ventricle, a condition that can be determined in vivo by alterations visible in the electro-cardiogram in an animal placed in rarefied air. The resistance to the contraction of the right auricle and retardation of the right ventricular systole and more rapid contraction of the left ventricle can be followed.

GUEYSE-PELLISIER, of Paris, described the histological effects when 1-2 c.cm. of oil were injected into the trachea of rabbits or 10-15 c.cm. into dogs of middle size. The oil is immediately atomised and reaches the air cells, where it is easily found six hours after injection. After several days the globules undergo lipolysis, the pulmonary parenchyma is more or less hypertrophied, and soon all trace of oil disappears.

E. ABELOUS, of Toulouse, discoursed on secretin, whose function he regards as very wide and general, and destined to activate metabolism as a whole. Its injection augments the autolytic power of the tissues, the urine contains more salts and nitrogenous matters, the respiratory exchanges are greatly increased, the blood-sugar and the blood-cholesterol augmented, and that of the liver diminished.

J. CAMUS, of Paris, described the making of permanent biliary fistulæ, with or without cholecystotomy. To get a good result the common bile-duct must be well isolated for a considerable length and the sphincter of Oddi removed, with a lozenge-shaped part of the duodenum, before it is stitched into the abdominal wall. The duodenum is then carefully closed. Hæmorrhagic pancreatitis can be produced experimentally by injecting bile or intestinal juice into the duct of Wirsung.

J. CAMUS and G. ROUSSY, of Paris, showed dogs with experimental lesions of the base of the brain in the region of the hypophysis without injury of this organ itself. There was permanent polyuria—four or more litres daily; considerable genital atrophy; infantile penis and testes very small, with marked adipose accumulation.

According to ABELOUS and F. SOULA (Toulouse) the spleen has a cholesterinogenic function. The blood contains more cholesterol after intravenous injection of secretin, and there is no increase after excision of the spleen. The splenic vein blood in vivo contains more cholesterol than the splenic artery. Splenic pulp in suspension incubated in vitro with 2 per cent. sodium fluoride shows increase of cholesterol, the sources being chiefly cholic acid and soaps, the transformation being effected by a ferment which is found in a filtered fluorated watery splenic solution. Amongst other organs only the liver and nerve tissue—but in much less degree—form cholesterol; the adrenals, thyroid, kidneys, ovary, and genital glands and muscles have no such power—they destroy cholesterol.

The next meeting of the congress will be held in Edinburgh in 1923.

HAMBURG: GERMAN PHYSIOLOGICAL SOCIETY.

This society held its meeting at Hamburg from May 26th-28th.

R. PLAUT, of Hamburg, showed the pelves of rabbits and guinea-pigs (9-13 weeks old) of both sexes, fed with ether-extracts of cows' ovaries. The effects were produced only with extract of the corpora lutea. The extract caused change in the form of the pelvis, which was similar to that of the adult animal; there was a widening of the upper symphyseal angle, and an approach of the upper margin of the symphysis to the promontory.

R. DITTLER, of Leipzig, described a means of sterilising the female organism by a humoral method. By introducing parenterally living spermatozoa spermatotoxic substances are formed and are present in the blood; thereby it is possible to make adult female animals temporarily incapable of becoming impregnated in the normal way. In order to arrive at a sufficient concentration of the antibody at the place of meeting between the ovum and sperm—i.e., in the ovum itself—there must be several repetitions of the introduction of the antigen; the whole preliminary treatment requires at least 6-7 days. The sterility may last four months or longer, and is completely reversible. A current pregnancy is not interrupted by a corresponding sperm treatment. After several injections of large doses of human spermatozoa the animal experimented on shows the normal capacity for fertilisation with spermatozoa of its own species.

Reviews and Notices of Books.

ATLAS FOR ELECTRODIAGNOSIS AND THERAPEUTICS.

By F. MIRAMOND DE LAROQUETTE, M.D. Authorised translation by MARY GREGSON CHEETHAM, with Foreword by ROBERT KNOX, M.D. London: Baillière, Tindall and Cox. 1920. Demy 8vo. With 69 plates and figures in the text. Pp. xvi. + 180. 15s. net.

THIS work was prepared with the object of providing, in convenient form, an account of the anatomical facts necessary as a basis for the practice of electrodiagnosis and physiotherapy. One half of the book deals with the muscles, nerve trunks, and plexuses. Under the heading of each muscle are described the origin, insertion, action, nerve-supply, position of motor point, and the strength of the galvanic current required to cause a minimal contraction with both anode and kathode. The position of the nerve plexuses, the course and distribution of the nerve trunks, and the regions where the latter are accessible for electrical testing are indicated. Numerous plates illustrate dissections of the muscles and nerves, the position of the motor points, and the areas of cutaneous nerve-supply. Notes are added on points to be observed when testing for electrical reactions, and tables are appended giving the author's "coefficient of excitability" of different muscles and nerves. About one-third of the book is occupied by descriptions of the joints, special attention being paid to their mechanical function and range of movements. A short account is given of the motor and sensory tracts of the central nervous system and of the structure of the skin.

The atlas will be extremely useful to those who are learning electrodiagnosis and physiotherapy. The various anatomical and electrical data necessary for the study of these subjects are scattered through various text-books, while the work under review presents them in a compact form, and in addition contains original work of the author on the electrical excitability of the various muscles and nerves. The work is clearly translated and is easy to understand. To English readers the anatomical nomenclature may be confusing, but this will not impair the usefulness of the book. The translation of some terms are unfamiliar—for example, "electrical swab," by which is evidently meant "testing electrode." On p. 7 Burdock should read *Burdach*.

VERGLEICHENDE ANATOMIE DES NERVENSYSTEMS.

Die Leitungsbahnen im Nervensystem der Wirbellosen Tiere. Von Dr. E. B. DROOGLEEVER FORTUYN, Lector der Histologie, Reichs-Universitt, Leiden. Erster Teil. Mit 116 Abbildungen im Text. Haarlem: De Erven F. Bohn. 1920. Pp. 370. 25s.

THIS is the first part of a work on the Comparative Anatomy of the Nervous System, projected by C. V. Ariens Kappers and the author. It was undertaken at the request of Dr. Kappers, who will deal with the Nervous System of the Vertebrates. It is not a com-

pendium on the structure of the nervous system in the invertebrates, but the subject is something far more restricted and, in some senses, more difficult, viz., the conducting paths in the nervous system of invertebrates, which postulates a wide knowledge of the outer and inner anatomy of invertebrate structure. The author has been at immense pains to collect, sift, and put together the various and very scattered references to this subject which are to be found in the comprehensive literature which he cites. He has supplied a great want in invertebrate nervous physiology, and is warmly to be congratulated on the result of his painstaking and highly successful effort. Part of the expenses were defrayed by the Dutch Minister of Art and Sciences.

The idea of conducting paths is clearly one obtained from vertebrate anatomy and physiology, where the types of central nervous system are few, and the conducting paths—at least the peripheral—are obvious and well defined. Far otherwise is it in most invertebrates, in which it is sometimes difficult to determine what part of the nervous complex is to be called central and what peripheral. The nerves for the most part are non-medullated, and the methods for their study and distribution correspondingly restricted, although the methylene-blue and Cajal methods have in many cases proved most useful. Moreover, the fundamental conception of the independence of the neuron and the relation between neurons by contiguity and not by continuity scarcely obtains in the invertebrates, where the nerve cell or neuron may have two or more processes which anastomose with similar processes from adjoining nerve cells, scattered under the epithelium or in the walls of viscera, forming wonderful nerve nets with the cells at the nodes, permitting of conduction it may be in several directions. Nor is the nerve cell the only formed element in the invertebrate nervous system where we have the doctrine of the uninterrupted connexions of the neurofibrils propounded by Bethe. Conduction is far more diffuse—especially as seen in the coelenterata—though each ganglion cell has only a few direct connexions with adjoining nerve cells, resulting in certain definite groups and a certain limitation in the direction of conduction. The author gives a systematic exposition of his results from porifera or sponges, which do not appear to possess a nervous system at all, to arthropoda and cephalopoda, ending with a short account of amphioxus. As a rule, coelenterata possess a nervous system chiefly composed of a subepithelial plexus of ganglion cells, which anastomose by means of broad processes, while other processes serve for the innervation of muscle cells and others pass directly to the basal or centripetal processes of epithelial cells belonging to receptive sensory cells, something corresponding to the olfactory sensory cells in vertebrates. Even amongst what appears so well-defined a group as the "vermes," the structure of the nervous system in its different classes and orders is so little uniform that it is not possible to unfold a general type, hence the author requires about 90 pages and many diagrams to set forth what he has to expound. To the mollusca 60 pages are given, and even then the author has to admit how large are the lacunæ in our knowledge as to conduction in even the highest group—the cephalopoda. Amongst echinoderms, although we know something of their nerve reactions and intensely interesting physiology, the author is shocked that we know so little about the paths of conduction. Nor are the causes far to seek in all the five classes of this group, and so the story is soon told in 10 pages. A specially full account (over 150 pages) is given of the arthropoda, illustrated like other groups by many schemata, which are helpful in enabling the reader to follow the rather intricate connexions which obtain here as elsewhere. The sense organs come in for a careful study as the primary receptive organs for the origination of impulses.

Altogether this is a most praiseworthy and illuminating exposition of what is known of the nerve-conducting paths in invertebrates. To zoologists especially it will be welcome, and to those few physiologists who devote attention to comparative physiology of the invertebrates. What strikes one in looking over the very extensive

bibliography given by the author is the paucity of memoirs bearing English or American names. In this volume is laid the foundations on which, we hope, will be built many fascinating inquiries on the nervous physiology of invertebrates, an immensely wide and almost virgin field of investigation.

DIAGNOSIS OF BACTERIA AND BLOOD PARASITES.

By E. P. MINETT, M.D. Third edition. London: Baillière, Tindall and Cox. Pp. 94. 4s. 6d.

THE intention of the author of this small volume, who is government medical officer of health in British Guiana, is "to provide a pocket reference book for use in the laboratory by students and practitioners who may not have time to consult standard works on the subject." The need for such a book is no doubt often felt by those who work in improvised laboratories, remote from large towns and libraries, and may be felt by those who, whilst within easy access to standard works, like to possess within a small compass brief descriptions of the principal technical procedures. Such a book, to be of value, must be accurate and reliable from the first page to the last; it should contain an account of the best technique for each subject it touches upon; the descriptions ought to be concise and the phraseology clear and unexceptionable; and, finally, wherever it is impossible to give at least sufficient information to enable the practitioner to carry out successfully the operations indicated the subject should be omitted.

The volume under notice fails in all these respects. With regard to accuracy, on p. 9 *B. welchii* is classed as a motile organism, though this is qualified later on p. 10 by the statement that it is often non-motile. "*B. enteritidis sporogenes*" is now generally regarded as a mixture of organisms, though the author includes it (p. 9) as a definite species. The account of *vibrio septique* omits mention of the most characteristic property of this organism—namely, the formation of long filaments in the peritoneal sac of inoculated animals. The medium recommended for the cultivation of *B. influenzae* is blood agar, in spite of the large amount of recently published work on "altered blood" media. For the investigation of a suspected case of cerebro-spinal fever the author recommends that a throat-swab be taken; a lumbar puncture would be more to the point. Ultramicroscopic organisms are described as "substances," a term properly applied to inert matter.

These are sufficient examples of errors, omissions, and the improper use of words to indicate that the book may mislead uninstructed readers.

DISEASES OF THE NOSE AND THROAT.

Fourth edition. By HERBERT TILLEY, B.S. Lond., F.R.C.S. Eng. London: H. K. Lewis and Co., Ltd. With 74 plates and numerous text illustrations. 1920. Pp. xx. + 844. 25s. net.

THIS book has already passed through three editions, and by so doing has proved that its value is well appreciated. The work has grown with each successive edition, and the present volume again shows a notable increase in size. The fresh illustrations are equal in value and execution to those which they supplement, and have increased in quantity. An attractive part of this edition is that devoted to the tonsils, both the development of the structure, its pathological states, and function being carefully reviewed. Much more attention is paid to the operation of tonsillar enucleation than might at first sight appear warranted on account of its relative simplicity. But the present views of specialists in diseases of the throat, nose, and ear, are more in line with those of general physicians than was the case in previous years. Now the relatively small and soft tonsil is no longer regarded as innocuous, but the tonsil is recognised as the great portal through which much disease finds entry into the system. Hence a description as full as Mr. Tilley's is really quite advisable. There are naturally different views about such matters as paroxysmal sneezing and rhinorrhoea, and we are not quite with the author in considering the terms synonymous, or in holding that the conditions are due always to the same cause. On p. 42

we are glad to see a useful and pertinent warning against carelessness in intranasal treatment by operation and the ill-effect which may ensue. On p. 160 Mr. Tilley advocates the employment of powdered chalk as a dentifrice during the administration of mercury. This recommendation is at variance with the theory of many dental surgeons that powdered chalk is injurious by damaging the mucosa of the fang-socket and so leading to Riggs's disease.

We congratulate the author upon the success of his arduous task of revision, and have no hesitation in recommending his book to the practitioner as well as to the prospective specialist.

CURIOSA DE MÉDECINE.

By Dr. G. J. WITKOWSKI. Paris: Libraire Le François. 1920. Pp. 272. Fr. 6.

Dr. Witkowski is well known as a diligent seeker in the by-ways of medicine and anatomy as exemplified in art and literature, especially of Mediæval and Renaissance times. In his latest book now before us he has collected a number of odd incidents, epigrams, pictures, carvings, and the like, mainly of that kind to which is applied the term "curious" in secondhand booksellers' catalogues, but, as a whole, we cannot say that the collection is particularly interesting. Items worth noting are p. 35, a reproduction of a drawing by Louis XIII. executed at the age of 6, which certainly shows astonishing precocity, and, moreover, resembles in execution such drawings by primitive man, as, for instance, the well-known *Femme au renne*, of the "Reindeer Period," the art of the comparatively modern child thus reproducing the art of the childhood of the human race.

On p. 29 Dr. Witkowski gives his reasons, together with an explanatory diagram for thinking that, contrary to the expressed opinions of the 31 medical men who signed the report of the post-mortem examination on Henri IV., the mortal blow was the first and not the second. On p. 143 is a reproduction of a most interesting photograph found in a German officer's baggage of the Emperor William and the King of Saxony. The Emperor's photograph clearly shows his withered left arm, which is generally disguised in official portraits. The paralysis is due, says Dr. Witkowski, to some obstetrical injury and not to infantile paralysis. The punning latin distich on p. 227 entitled "Advice to Youth," is printed as follows:—

"Quid facies Veneris cum veneris ante?
Ne sed eas; sed eas, ne pereas per eas."

but obviously there should be a second "facies" after the word "Veneris," both to complete the hexameter and to carry on the verbal equivoque.

THE ESSENTIALS OF HISTOLOGY.

Descriptive and Practical. For the Use of Students. Eleventh edition. By Sir EDWARD SHARPEY SCHAFFER, F.R.S., Professor of Physiology in the University of Edinburgh. London: Longmans, Green, and Co. 1920. Pp. 577. 14s.

ORIGINALLY published in 1885, now greatly expanded and illustrated by 720 figures in the text, many of them in two well-chosen colours, and several photographs, the illustrations judiciously selected or reproduced from original preparations, the whole forms an admirable conspectus arranged in 50 lessons, wherein by far the largest part is descriptive. Shorter details as to the actual "preparations" or "slides" which the text describes and elucidates precede each lesson, intended to occupy from one to three hours of practical work in a class under the direction of the teacher. The pupil is not distracted by a multiplicity of methods, for only those are recommended upon which experience has proved that dependence can be placed. So numerous and faithfully reproduced are the illustrations that a student in revising his work by glancing over the pages can through the eye rapidly cause to recur to memory the actual pictorial impressions as seen with the microscope. The illustration showing the successive effects of water and other reagents upon a red blood corpuscle—printed in red—might give a false impression, as decolorisation is so

marked an effect of certain of these reagents. So also in the figures of blood corpuscles of the frog and those of amphibian erythrocytes the red is very bold and arresting, but the actual faint yellowish colour tinge in the original corpuscle is missing. In edition after edition new figures have been added, so that there are but few parts of the body corporate whose structure is not represented pictorially. The most condensed and the most difficult lessons are the four on the central nervous system, while three lessons are given to the eye, requiring 11 preparations to be made.

The Essentials contain all and perhaps more than all the student requires to meet the exigencies which befall him in his medical career.

A TEXT-BOOK OF HISTOLOGY.

Second edition. By HARVEY ERNEST JORDAN, A.M., Ph.D. London and New York: D. Appleton and Co. 1920. With 594 illustrations in the text and 4 plates. Pp. 857. 25s.

THE appearance of a second edition of this text-book less than four years after its publication is proof that it has found favour in medical schools. This edition has been considerably improved by the substitution of drawings for some of photomicrographs, though, even now, a few photographs of doubtful value have been retained. Another welcome addition is the section on the directions for laboratory work, which gives a very satisfactory scheme for a course of practical histology.

This text-book will fulfil all the requirements of the medical student. It is clearly written and adequately illustrated, and while it is not too long or complex, everything which it is necessary for the student to know is included.

ESSENTIALS OF SURFACE ANATOMY.

Third edition. By CHARLES R. WHITTAKER, F.R.C.S. Edin., F.R.S.E. London: J. and A. Churchill. 1920. With 17 plates of 27 figures. Pp. 80. 7s. 6d.

THIS handbook deals shortly with surface anatomy in a clear and dogmatic manner. The blood-vessels and nerves are dealt with in the first two sections, regional anatomy being considered subsequently. Cerebral topography is treated with some fullness, and Chiene's method described and illustrated. Addison's markings are employed in the abdomen. There are some small differences between the teaching in this book and that usually accepted in London, but there is room for variations of this sort. Altogether the book seems to us a reliable guide for those who wish to "get up" their human landmarks.

GREEK SCIENCE AND MODERN SCIENCE:

A Comparison and a Contrast. Being an Inaugural Lecture delivered at University College, London, on May 12th, 1920, by CHARLES SINGER, Lecturer on the History of Medicine. London: University of London Press. 1920. Pp. 22. 1s. 6d.

In this interesting lecture Dr. Singer points out how Greek science "was from its birth inextricably interwoven with philosophy," but that modern science passed through its earlier stages of development without this relationship. Science in mediæval times was limited on every side and forbidden the right of speculation, but this limitation had a share in building up an effective apparatus for research. Ancient science came to "failure and bankruptcy" because, except in the case of mathematics, Greek writers set down only their conclusions, whereas modern scientific writers record, not indeed entirely, but for the most part, their investigation processes. Dr. Singer says of a modern scientific worker's paper: "He tells us nothing of how he embarked on many different lines of work and abandoned them as unprofitable or too difficult." Surely this is too sweeping a statement; at all events, there is one case to the contrary and that is Lister, who has left on record the many trials, difficulties, failures, and lines of work in which he toiled before perfecting his system. As a general statement, however, it may pass. But with Dr. Singer's final plea we can all agree—namely, that for the record of processes. "By the amount to which our processes are clearly and succinctly recorded, by

so much do we ensure the permanence of our work, by so much can we guarantee that our successors can begin where we leave off." On p. 13 Dr. Singer makes a statement which we do not consider altogether fair. He recalls how scholars ransack Eastern monasteries or the dustheaps of Egypt for any fragment of Greek literature, but "the works of our first scientific thinker, Roger Bacon, lie here at hand, unedited, forgotten, neglected." Surely the works of Roger Bacon are now in process of editing? A scheme for so doing was certainly started in 1913, a year previous to the occasion of Bacon's seventh centenary—i.e., in 1914. A committee, with the Chancellor of the University of Oxford as its honorary president, was formed to carry out the scheme, but though the war may have put a stop to the editing it is surely not the case that Bacon's works are either neglected or forgotten.

TEXT-BOOKS ON CHEMISTRY.

A System of Physical Chemistry. By WILLIAM C. MCC. LEWIS, M.A.R.U.I., D.Sc. Liverp. London: Longmans, Green, and Co. In three volumes (second editions): Vol. I., 1918; Vols. II. and III., 1919. Pp. 494, 404, and 210. 15s., 15s., and 7s. 6d. respectively.—This is a masterly work in three volumes presenting with some detail the modern developments of physical chemistry. The first volume deals with thermodynamics (the laws and relationships which govern the quantitative transformations of energy), the second volume with the kinetic theory (the molecular constitution of matter), and the third volume with the quantum theory (statistical mechanics). The direct bearing of certain branches of the subject on the progress of medical science is illustrated in many chapters, as, for example, in those on capillary action, colloids, and catalysts in Vol. I.; osmotic pressure, ion activities, adsorption in Vol. II.; and radiation phenomena in Vol. III. It is impossible to carry on satisfactorily physiological and biological researches without a knowledge of the principles underlying physical chemistry, and these volumes will be referred to with undoubted advantage by workers in this field.

Pharmaceutical and Medical Chemistry. By SAMUEL P. SADTLER, Ph.D., LL.D., VIRGIL COBLENTZ, Ph.D., F.C.S., and JEANNOT HOSTMANN, Ph.G. Fifth edition, revised and rewritten. London and Philadelphia: J. B. Lippincott Company. Pp. 766. 21s.—This text-book, intended for the use of medical and pharmaceutical students, covers considerable ground, beginning with Part I. (Elementary Physics), succeeded by Part II. (Chemistry of the Non-Metals), then Part III. (Chemistry of the Metals), and finally Part IV. (Organic Chemistry). The three authors have formed a very successful collaboration, and each is an admitted authority on the subjects which he contributes. The revisions are in conformity with modern advance, much of the new ground covered being an outcome of chemical developments arising through the war. This is particularly the case with the sections dealing with the manufacturing side of chemistry. The sections on organic chemistry show also a commendable effort to bring the book into modern lines. The carbohydrates come in for full treatment, as do the alkaloids. There is an excellent account of electrolysis and its applications. The pharmaceutical sections are based on the U.S. Pharmacopœia. The book gives evidence of labour, thought, and care, and should prove a valuable source of reference and study to pharmacists and medical practitioners in this country also.

Organic Chemistry for Students of Medicine. By JAMES WALKER, LL.D., F.R.S. Second edition. London: Gurney and Jackson. 1919. Pp. 332. 10s. 6d.—The treatment of the subject is severely chemical, and while affording a good foundation for assisting future study when the importance of a knowledge of organic chemistry dawns, as physiological and biological questions are approached, the work gives but a scanty reference to the medical significance of the substances described. Theoretical questions are entered into, constitutional formulæ form a feature, and technical operations—e.g., the distillation of coal, with a section

on coal-tar—are described in some detail. All this is a good deal to force into a six months' course of chemistry, and there is always a difficulty in narrowing the subject in order to keep within the requirements of the student of medicine preparing for his first professional examination. But we quite agree with the author that the student should be made to realise that he has not done with chemistry when he has passed this examination.

JOURNALS.

Journal of the Royal Army Medical Corps.—In a paper on Sick Wastage in the August issue of this journal Colonel A. B. Soltan discusses the diseases that caused loss of service to the army in France. Of the 106,267 cases passing through certain casualty clearing stations in 1917 Colonel Soltan considers that approximately 46,500, or 44 per cent., suffered from preventable dirt diseases. Thus 25,000 had skin diseases, 10,000 of them scabies, and 10,000 inflammation of connective tissue. These diseases are pretty easily treated if discovered by careful exact frequent inspection in their early stages. If they are to be prevented men must have sufficient baths and clean underclothing. Colonel Soltan estimates that there were 21,500 cases of trench fever. Five thousand are so named, and there are, moreover, 15,000 cases reported of pyrexia of unknown origin (80 per cent. at least trench fever); from the 5000 labelled myalgia Colonel Soltan takes 3000 as trench fever, and from the 5000 cardiac and debility cases 1500 more, and thus arrives at the figure of 21,500. To prevent this high morbidity from dirt diseases he urges that in future each unit shall have a standard pattern disinfectant, where men shall simultaneously bathe, have their outer clothes disinfected, and be given clean underclothing; then "the louse and the acarus will not again play havoc." He also urges the appointment of standing boards of specialists at the bases to allot to suitable work men partly disabled. Enthusiasm carried many feeble men through enlistment; they broke down on service and drifted continually through the hospitals, unfit for the line. These standing boards proved a great success in Egypt. Amongst the same group of casualties (106,267 in all) there were 7000 venereal cases, 3000 trench feet, 258 tubercle, and 3500 each of influenza, bronchitis, and mental disease. The second part of Colonel Soltan's paper is also very important, and discusses where these cases should be treated with a minimal loss of service. He claims that in the army zone, if at all possible, is the best place. Evacuation of the sick is unfortunate in its results. The sick retained are more anxious to get well; they rejoin their own units more quickly and there become useful in a shorter time than do new men, with consequent improvement of the morale of their units. The man evacuated cost a great deal and was apt to become "hospitalised" and disinclined to return. It was well to have convalescent centres in the army zone. Thus the Fourth Army, which in the winter of 1917-18 made a C.C.S. a convalescent centre for each corps, returned to duty 20,000 men, of whom half would otherwise have been evacuated. Though holding perhaps the worst part of the line, this army kept its evacuations below those of the other armies. Men do not get quiet nowadays even in base hospitals, for these, too, are subject to hostile aircraft attack. In the same number of the journal Major Angus Macdonald states that the last epidemic of malaria in England occurred in 1857-60; that malaria prevalence in England is not regular but intermittent and depends on the presence of carriers and a mean monthly temperature of 59° or over. In 1857-59 the mean monthly temperatures at Greenwich for June, July, and August, were all over 59°, and malaria was prevalent. In 1860 the mean temperature of each of these months was under 59°, and the prevalence of malaria in England ceased. In 1917-18-19 malaria appeared in England after the mean temperature had been for a month above 60°. All were *P. vivax*.—Lieutenant-Colonel G. B. Crisp gives a quantity of useful advice as to outfit and financial conditions to officers going to Hong-Kong, which he describes as a delightful station.—Lieutenant-Colonel G. H. Younge discusses 180 cases of appendicitis which occurred in three years in his hospital at Grantham.

The Bulletin of the Naval Medical Association of Japan for June, 1920, contains an interesting article by M. Ishihara, Surgeon-Lieutenant-Commander, I.J.N., on the Effect of Experimental Extirpation of the Thyroid Body. From his observations on young rabbits from which the thyroid was removed the author arrived at the following conclusions: 1. Excision of the thyroid in young rabbits is followed by enlargement of the thymus, probably due to a compensatory action existing between these two organs. 2. Differing from the views advanced by Hofmeister and v. Eiselberg, growth and metabolism in rabbits are not interfered with by extirpation of the thyroid. 3. Degenerated corpuscles of Hassall are met with more frequently in the thymus of normal than in that of dehydratized rabbits; and removal of the thyroid is not necessarily followed by enlargement of the pituitary.

FRENCH SUPPLEMENT TO THE LANCET

Under the Editorial Direction of

Professor CHARLES ACHARD,

AND

Dr. CHARLES FLANDIN, D.S.O.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY
OF PARIS.

CHEF DE CLINIQUE A LA FACULTÉ DE PARIS.

FRENCH RESEARCH ON GAS GANGRENE.

By E. SACQUÉPÉE,

MÉDECIN PRINCIPAL DE LIÈRE CLASSE; PROFESSEUR AT THE
VAL-DE-GRÂCE.

THE appearance of numerous cases of gas gangrene in connexion with wounds received in the war has been a great surprise to French medical men. As a result of the progress of modern methods of treatment this malady had nearly disappeared from peace-time practice. The present medical generation hardly knew it except by name never having had occasion of observing it.

At the outset it created some confusion, but also a firm determination to get a nearer acquaintance with this very serious complication in order to fight it better. Based on clinical observation, these efforts have aimed above all at elucidating the pathogeny of the accidents. It was clear that the complication was of infectious nature, and it was therefore first of all necessary to find out the species of microbe which were responsible for the accidents. Once this were accomplished it would be possible to think out some specific therapy with which to meet them.

We propose to explain the researches made in the course of the war in the same order—clinically ascertained facts, pathogenic studies, specific treatment.

I. Clinically Ascertained Facts.

We must first briefly sum up the clinical facts in order to show what French doctors have understood under the name of gas gangrene. The complaint being previously hardly known, some mutual agreement as to the connotation of words was above all necessary.

By the name "gas gangrene" we mean an extremely grave complication of the wounds, characterised at once by local and by general symptoms. The local symptoms are essentially gaseous infiltration, œdema, deterioration of the tissues (especially muscular) with gangrenous tendency, and a characteristic smell. The importance of these great symptoms varies from case to case; hence the manifold clinical types. In addition, various types of erythema (especially bronzed), phlyctenoses, &c., may be observed.

The general symptoms are constant and are marked by extensive poisoning, characterised especially by increased rapidity and extreme weakness of the pulse, dyspnoea without thoracic lesion, earthy—sometimes icteroid—colour of the skin.

Unless treated by specific means, this very serious affection proves fatal in about 75 per cent. of cases within a day or two.

From this summary description it follows that the facts studied in France under the name of gas gangrene correspond above all with the serious forms of gaseous infection of wounds. Besides the latter there is a large number of other gaseous infections, far less serious, not accompanied by the general phenomena described above, amenable to purely surgical intervention. In view of their comparative benignity these lighter forms have been studied very much less.

The clinical picture just described had to serve as a basis to the pathogenic studies. The germs supposed to be the agents of the gas gangrene had really to be capable of reproducing the double series of symptoms—local manifestations and general intoxication.

II. Pathogenic Studies.

In order to get the full advantage of the progress made with regard to the pathogeny it is convenient to specify what our knowledge of the matter was before the war.

It is well known that, following Davaine in his study of "experimental septicæmia," Pasteur showed that this

infection is due to the *Vibrio septique* (1877). Chauveau and Arloing (1884) then demonstrated that this same germ also existed in gas gangrene in human beings.

Clinical researches into the question then became very difficult in France, since the first effect of the application of Pasteur's principles to surgery was to render gas gangrene extremely rare.

On the other hand, in foreign countries, especially in Germany and America, the study of certain new facts was possible. Welch and Fraenkel and, following them, a number of other authors, charge Welch's bacillus (the *Bacillus perfringens* of French writers) with being the main cause. According to these works the *Vibrio septique* seems entirely wiped out as far as its influence goes.

Progress of Knowledge During the War.

Such was the state of our ideas about 1914. We are now in a position to follow their development in the course of the war.

During the first stage the predominant theory of the pre-war period was followed. *Bacillus perfringens* plays a leading part. Indeed, its importance is such that there is hardly any question of other microbes. Weinberg, Sartory and Spillman, Doyon and Yamamouchi, and Orticoni, all invariably, or nearly invariably, find the *B. perfringens*.

The second stage opens with our first work in May and June, 1915, based on the following principle: the best criterion of a pathogenic species is constituted by its ability to reproduce the malady experimentally. Now, the *B. perfringens* can reproduce the local lesions of the gangrene, but it cannot be made to produce a potent toxin. There is, therefore, reason to examine whether there are not in the gangrenous tissues other pathogenic germs which comply better with the experimental criterion.

In the great majority of cases investigations in this direction gave an affirmative answer. We found either the *Vibrio septique* or a new bacillus which was later to receive the name of *Bacillus bellonensis*. These two germs are pathogenic for animals, in vitro they provoke the formation of very active toxins, experimentally they produce lesions closely analogous to those observed in cases of gas gangrene in man.

Working on similar lines, Lardennois and Baumele then proved the frequency of the *Vibrio septique* (about one-quarter of the cases), Weinberg and Séguin also announced the existence of the *Vibrio septique* in certain gas gangrenes, and also of another germ, called by them *Bacillus œdematiens*, probably identical with the *B. bellonensis*.

In this way it gradually became clear that gas gangrene was associated with three species of organisms—*Bacillus perfringens*, *Vibrio septique*, and *Bacillus bellonensis*, acting either alone or in association. And the Inter-Allied Surgical Conference, meeting at Paris, adopted analogous conclusions:—"Among the germs met with there is reason to retain the *Vibrio septique*, *Bacillus bellonensis* (the exact relations between the *Bacillus bellonensis* and *Bacillus œdematiens* are not yet made clear), and *Bacillus perfringens*."

Confirmation of the Pathogeny Adopted.

How well founded was this conception was to be proved later by the experimental application of seropathy, thanks to the proof afforded by the "protected guinea-pig," which de Lavergne discusses in another article. It is well known that the tissues of typical human gas gangrene are always pathogenic for the guinea-pig, which succumbs on inoculation. If the above-mentioned germs are really the essential agents of the affection it must be possible to "protect" the animal, if it is inoculated, simultaneously with the gangrenous tissues, with the three serums respectively specific to each of the three germs. Experiment confirms this; inoculation with the three serums, antiperfringens, antibellonensis, and antiseptique, carried out at the same time as with the infectious product, is enough to protect the animal in 96 per cent. of cases.

It is therefore safe to conclude that the pathogeny adopted is certainly correct in the great majority of cases. The other germs described as existing in gas gangrene, such as Weinberg and Séguin's *Bacillus fallax*, are therefore of only very small importance.

To make our conception quite clear we add here the results of the analysis of 121 cases under our personal supervision. *Bacillus perfringens*, 82 per cent.; typical *Vibrio septique*, 28 per cent.; non-typical *Vibrio septique* 11 per cent.;

Bacillus bellonensis 35 per cent. The germs are very often associated in pairs.

If we limit ourselves to the facts recently discovered during the war, we need not repeat the history of the *Bacillus perfringens* and the *Vibrio septique*, as both are known from previous investigation. In particular we knew that the *Vibrio septique* is not only highly pathogenic but also highly toxic; the researches of Leclainche and Vallée had shown this.

The Bacillus Bellonensis.

On the other hand, the *Bacillus bellonensis* being a new species it is necessary to describe it briefly. It is often found to predominate, sometimes it is even the sole species of anaerobe in a rather special clinical form—viz., white erysipelas.¹ In the other forms it is more usually fairly difficult of detection in the midst of other species of anaerobe better adapted to artificial surroundings.

The *Bacillus bellonensis* is a strictly anaerobic germ. It presents the appearance of a straight or slightly curved bacillus in the organism, polymorphic in artificial mediums, slightly or not at all mobile, ciliated, sporulated (oblong or oval spores), colours easily with Gram's solution.

Cultures develop easily. In a deep glucose agar stab culture the colonies appear in 24 hours, formed of a yellow-brownish, opaque central nucleus, with a paler nimbus formed of unequal filaments easily visible on enlargement. These colonies clear up and seem to dissolve after three or four days.

In glucose broth culture is visible in 24 hours, at first homogeneous disturbance with gaseous discharge, then appearance of flocculent deposit with clearing of supernatant fluid, the whole being complete within 36 or 48 hours.

Pathogenic qualities are highly developed, especially in the guinea-pig and the rabbit. In this connexion it is useful to distinguish two types of microbe which cause fairly different lesions in the animal.

The first and most frequent type causes in life the formation of a hard and very extensive oedema; death supervenes quickly, sometimes within nine hours. Autopsy reveals a huge, tremulous, colourless, or faintly tinted oedema, infiltrating the tissues to a great distance, in some places from 1 to 2 cm. thick; gaseous infiltration and muscular lesions are slight or nil. In such cases the germs are always scarce, except at the point of inoculation.

With the second type inoculation produces a local tumefaction, gaseous crepitation, coldness of the limb, various colours (violet, livid, ham-coloured), sometimes phlyctenules. On autopsy very extensive, rose or brownish gelatinoid oedema, with slight but appreciable gaseous infiltration.

Both types are toxic, above all the first. The two or six days' old filtrates (Chamberland's candle) of cultures in a liquid medium are pathogenic for the guinea-pig and the rabbit, in doses varying according to the specimens and conditions of culture; for the guinea-pig the fatal subcutaneous dose varies from 1/600 to 1/2 c.cm.; the sole lesion that can be observed consists in an enormous colourless oedema.

The *Bacillus bellonensis*, then, constitutes a highly pathogenic, very toxic species, capable of reproducing perfect gas gangrene experimentally.

III. Specific Treatment.

Acquaintance with the three essential species, *V. septique*, *B. bellonensis*, *B. perfringens*, makes it possible to consider the specific serotherapy successfully.

The first attempts at serotherapy were not very effective, since they really aimed exclusively at the species mentioned at the beginning, *B. perfringens* and *V. septique*, taking no account of a third agent of capital importance, the *B. bellonensis*. It is only by applying a specific serotherapy either against all three germs or against the germ involved in each particular case that a practical result can be reached.

The preparation of the serums follows the general principles already established in bacteriology. For toxic germs it is important to prepare the animals for inoculation

of the toxic products; so far, indeed, the antitoxic serums prove more efficacious (antitetanus, antidiphtheria serums, &c.). On the other hand, when germs with feeble toxicity like *B. perfringens* are dealt with the procedure in preparing the serums is far less fixed.

By way of example let us cite the preparation of the antibellonensis serum. A horse is first inoculated subcutaneously with small doses of toxin (0.5 to 1 c.cm.), and the inoculations are continued, increasing the doses progressively up to one and a half or two litres. At this point direct inoculation into the veins takes place. In this way sufficiently strong serums are obtained to protect the animals for the experiment against 80,000 to 120,000 fatal doses of toxin. There is, by the way, no technical difficulty in obtaining more active serums, it is merely a matter of doses, toxin, and time.

Similarly, for the antivibrio serum, Jouan, of the Pasteur Institute, used toxin—i.e., filtered toxic cultures. As for the antiperfringens serum, Veillon, of the Pasteur Institute, prepared it by inoculation of living cultures.

Other serums have also been used—Leclainche and Vallée's polyvalent serum (antiperfringens and anti-septique), various serums by Weinberg and Séguin (prepared against the *Vibrio septique*, *B. perfringens*, and *B. oedematis* respectively), H. Vincent's polyvalent serum, prepared with the aid of various species of microbes met with in gas gangrene.

These various serums have been used for human patients. The really great difficulty was to know which serum was to be used in each case. In most of the cases it was decided to inject all three simultaneously, although this was evidently only a makeshift procedure. Even so, this method has given decided results, as we shall indicate below. But the discovery of some means of rapid pathogenic diagnosis was indicated, in order to get the pathogenesis and at the same time the treatment promptly on the right lines. In the last months of the war we attained this by means of the proof of the "protected guinea-pig." (See the article by de Lavergne.)

Results of Curative Serotherapy.

Without going into details at this place about the results obtained for each serum, we will simply recall those which are connected with the simultaneous application of the active serums against the *Vibrio septique*, *B. bellonensis*, and *B. perfringens*.

To take the curative point of view, 191 cases of gangrene have been treated, of which 136 were in full development and 55 at their commencement. As against 166 cures there were 25 deaths—i.e., a proportion of 13.09 per cent. For the sake of comparison it must be remembered that in the same regions the mortality in non-treated cases was about 75 per cent. It can therefore be seen in how far the curative treatment has been successful. It often operates in a really striking manner, for in a whole number of cases in which any surgical operation was undesirable, the shock of operation seeming to be bound to cause death, an energetic serum treatment brought about such an improvement that the operation could be carried out subsequently at leisure without any danger.

Results of Preventive Serotherapy.

From the preventive point of view serotherapy naturally proves itself still more powerful, and this has been the experience of a number of distinguished surgeons. Preventive treatment has been applied solely in the case of very severely wounded patients particularly exposed to gangrene (arterial wounds, extensive shattering of the buttock, thigh, &c.).

A series of wounds of the like nature, but not treated by serum, gave 7.2 per cent. cases of gangrene. Amongst the 319 cases treated preventively 4 cases—i.e., 1.17 per cent.—of gangrene were observed. Three further cases involved extensively mortified tissues (ligature, tourniquet) and were cured.

Here, again, the value of preventive serotherapy is evident, since it reduces the cases of gas gangrene to a very slight number of those wounds which are most exposed to it.

Summary.

As regards gas gangrene, French medical work has progressed along a logical and fruitful path of investigation. After having sufficiently defined the malady from the clinical point of view it went on to study the pathogeny. After having attained this it entered upon the path of therapeutic realisation by means of serotherapy, which has given the happiest results.

¹ Let us recall here the essential characteristics of this "white erysipelas," typical of the "oedematous forms" of gas gangrene. From the clinical point of view we note a considerable infiltration of hard, pale, oedema round the wound; muscular disturbances are slight, and gaseous infiltration small or non-existent, the smell is clearly perceptible. Evolution very rapid, nearly always fatal. On dissection of the member one finds enormous infiltration of pale or lemon-coloured liquid oedema, clearly marked muscular lesions, and slight, localised gaseous infiltration.

THE DIAGNOSIS OF BACTERIOLOGICAL TYPES OF GAS GANGRENE

BY MEANS OF SPECIFIC SERUMS.

BY DR. DE LAVERGNE,

PROFESSEUR AGRÉGÉ AT THE VAL-DE-GRÂCE.

DURING the war, gas gangrene was the subject of numerous works. Researches have finally culminated in a new pathogenic conception of this wound complication.

The Position attained in Pathogeny and Serotherapy.

At the present moment, indeed, gas gangrene is not considered a malady always identical with itself and having its specific microbe, but as a toxinfection with gangrenous and gaseous manifestations, which several anaerobic germs are capable of producing. Amongst these germs three are almost constantly met with, either the *Vibrio septique* or the *B. bellonensis* (or else *B. œdematiens*, very nearly related if not identical), or else the *B. perfringens*; two of these germs are often associated in the same lesion.

At the same time as the ætiology of this affection was being made clear, therapeutic serums were being prepared, an antiseptique serum, an antibellonensis serum (and an antioœdematiens serum), and an anti-perfringens serum.

It seemed, then, that we were in possession of an active serum against the pathogenic germ in a case of gas gangrene. And this is undoubtedly the case, provided that it is known which is the pathogenic germ conditioning the particular case of gangrene. We have three serums at disposal, but which is the appropriate one to any particular wound? Is the gangrene caused by the *Vibrio septique*, or *B. perfringens*, or *B. bellonensis*? It is here that the importance of the diagnosis—of the rapid diagnosis—of the bacteriological form of a case of gangrene lies.

*Early Bacteriological Diagnosis.**

The necessity of knowing promptly which is the pathogenic germ in each case of gaseous toxoinfection continues to exist in spite of attempts to get round the difficulty.

It was at first possible to believe that the aspect of the lesion and its clinical behaviour varied according to the nature of the toxoinfectious agent. It certainly seems that the œdematous forms of the gangrene (the type of which is white erysipelas) are due to the *B. bellonensis*, but purely œdematous forms are rare. Mixed cases with œdema and gas are very much more common, and it is then impossible to know which is the pathogenic germ when there is association. Slight clinical variations are unable to enlighten serotherapy.

It was next believed that in this bacteriological uncertainty it was best to inject a mixture of the three serums into the patient. This is certainly a rational procedure, but the importance of an early bacteriological diagnosis is none the less urgent. For it is obviously preferable to inject nothing but the specific active serum, the dose of which may then be increased and its therapeutic power raised accordingly. For this purpose an early bacteriological diagnosis is again necessary. How to obtain it?

The usual bacteriological methods cannot, as a rule, provide a diagnosis early enough. Quite apart from the time required by the isolation and identification of the anaerobic germs that are found, there are special reasons which often make the researches in gas gangrene particularly long.

To begin with, there is the circumstance that the growth on culture media of the toxic species (*Vibrio septique*, *B. bellonensis*) is often very scanty. Now, in order to separate the microbes as a preliminary to their identification it is necessary to start with a very small quantity of the pathological product. Hence the necessity of numerous subcultures and of multiplying the examinations for fear of error.

Further, we know now that the association of the germs of gas gangrene in the same wound is very common, so much so that repeated investigation is unavoidable before it can be said that only a single species of microbe is the cause.

Lastly, we know that *B. perfringens* is very frequently found in war wounds, whilst many of these wounds present no signs at all of gangrenous or gaseous infection. So much so that the presence of *B. perfringens* does not of itself imply that this germ has played an active part in the development of the infection. We must, therefore, ascertain its power by experimental investigations, a further cause of delay.

The classic methods cannot then provide that prompt answer which alone can guide the serotherapeutic treatment of an infection which runs its course in a few days. We were therefore led to seek for another way, and it seems that the method of diagnosis by means of the use of specific serums gives every satisfaction.

Principle of Method of Diagnosis.

Let us first give the theoretic basis of the method as we have used it in conjunction with Sacquépée.¹

The injection of a specific serum confers on the animal an efficacious, specific protection against the corresponding infection or toxoinfection. Now, an emulsion of fragments of a wound complicated with gas gangrene, when injected into the guinea-pig, provokes in that animal manifestations of that affection, because this emulsion, as a matter of fact, contains one of the three germs, *V. septique*, *B. bellonensis*, *B. perfringens*. But which of these three?

To ascertain this it is enough to inject this emulsion, which is pathogenic for the control, into three animals which have received, either beforehand or simultaneously, an injection of antiseptique serum, antibellonensis serum, and anti-perfringens serum respectively. It is then seen that two of these animals as well as the control develop signs of gas gangrene and die, whilst the third remains "protected." This is due to the circumstance that the experimental infection has been limited by the protective serum, and the nature of the serum indicates the nature of the corresponding germ which is the agent of the gas gangrene in that particular case.

Moreover, it may happen that the infection is mixed, and it is precisely by this method that this fact has been established. The experiment does not lose any of its precise character on increasing the number of animals protected by mixed injections of serums.

A Criticism Anticipated.

We shall describe the practical details to be adopted, but we must first anticipate a criticism.

The guinea-pig which receives a rich emulsion of a product of gas gangrene really receives a highly polymicrobial emulsion. Very numerous germs are, indeed, found in this liquid: streptococci, pneumobacilli, *B. proteus*, *B. tetani*. A priori, then, one might ask oneself whether the pathogenic action of these germs—indifferent as they are to gas gangrene—may not disturb the result of the experiment.

But there proves to be nothing in this objection. In the case of the guinea-pig neither the streptococcus, nor the proteus, nor the pneumobacillus, nor the tetanus bacillus produces any appreciable action within 24 or 48 hours, and in consequence they do not produce any morbid phenomena capable of simulating the development of gas gangrene. If, on the contrary, this polymicrobial product contains the agents of the gas gangrene, everything proceeds just as if a pure culture of one or two of these three species had alone been inoculated: appearance within the very first hours of a rapidly spreading local œdema, very marked, and growing with light crepitation from the twelfth hour, later injury to the general state and death towards the twenty-fourth hour, at latest in 36 or 48 hours. It will be noticed at the same time that the part played by *B. perfringens* in each particular case is cleared up. If the *B. perfringens* played no part at all in the gaseous infection it has no pathogenic effect; in the contrary case, it is observed that only the animals protected by the perfringens serum remain unhurt.

Practical Details of Methods.

Such is in principle the method of diagnosis by means of specific serums as applied to gas gangrene. Let us now consider the practical details of its working.

The emulsion must first be prepared, and the method is not immaterial. The favourite seat of the pathogen is

¹ Sacquépée et de Lavergne, Bulletins et Mémoires de la Société médicale des hôpitaux de Paris, Dec. 6th, 1918.

germs being the muscular tissue, this should be taken in preference to serum or cellular tissue. Moreover, in order to avoid the associated common-place germs the muscular fragment must be removed at the limit of the seat of infection. As soon as possible after removal the muscular fragment is teased in about 10 c.cm. of physiological saline. It is filtered through cotton, and the liquid is then divided into five test-tubes at the rate of 5 c.cm. per tube.

How are now the guinea-pigs to be "protected"? An injection of serum preliminary to the injection of the emulsion would retard the experiment. It is therefore preferable to inoculate serum and emulsion simultaneously after a brief preliminary contact. We take, therefore, the five tubes, each containing 1 c.cm. of emulsion. Tube No. 1 is left as it is; it will be inoculated into the control animal. To tube No. 2 we add 1 c.cm. of the antibellonensis serum, to tube No. 3 1 c.cm. of the antiseptique serum, to No. 4 tube 1 c.cm. of the antiperfringens serum, and to No. 5 1 c.cm. of each of the three serums. The whole is heated in the thermostat to 37° for 30 minutes. The contents of each tube are then inoculated into a guinea-pig belonging to a series of approximately equivalent weights.

Results.

Diagnosis is usually fairly clear after 12 hours, and after 24 hours there is no doubt at all.

In 60 per cent. of cases the result is schematic. By the twenty-fourth hour three animals are dead or dying—viz., the control and two animals inoculated with a single one of the three serums. Two are alive and vigorous, without even appreciable local lesions—viz., the guinea-pig which has received the three serums and one of those which has received a single serum. The nature of this serum indicates the nature of the pathogenic agent in the particular case of gangrene. The same serum which has protected the guinea-pig will protect the patient. Moreover, the results patent at the twenty-fourth hour are very often clear already at the twelfth, and serotherapy could have been put on the right lines from that time on.

In other cases (35 per cent.) the results are at first sight less schematic. The control dies, one of the three animals which have received a single one of the three serums dies also, and the two others survive or die slowly whilst presenting important local lesions, such as œdema, very often extensive, and gaseous crepitation. Finally, the guinea-pig protected by the three serums does not only not succumb, but does not even present any marked local phenomena.

These results must be interpreted as a case of double infection. The animal protected by the three serums has remained unharmed; two of the guinea-pigs with a single serum, having presented marked local phenomena, are only protected against one of the two infections: and the guinea-pig which is dead was not in any way protected by the serum which it had received. We have, therefore, all the elements wanted to recognise the germs associated in each case.

In 4 per cent. of cases all the animals succumb, not only the control, not only the animals protected by a single serum, but even the animal protected by the simultaneous injection of the three serums. In such cases, the rareness of which is apparent, neither the *V. septique* nor the *B. bellonensis* nor the *B. perfringens* is the cause. The gas gangrene is the work either of atypical *V. septique* or of *B. sporogenes* or some other aberrant germ.

Advantages of the Method.

The results obtained by this method of diagnosis by means of serums are parallel to those obtained by the usual bacteriological methods of separation and identification of germs. It retains the precious advantage of being infinitely more rapid and of replacing the blind method of serotherapeutic injection of the three serums by a method of seropathy in which only the useful serum or serums are injected, allowing the dose to be increased.

This method of diagnosis possesses another advantage. It gives the doctor confidence in curative serotherapy. By proving how often the guinea-pigs are efficaciously "protected" this test in medical experiment demonstrates all the benefits which the injection of the serum will confer on a patient attacked by the same infection as the guinea-pig.

Previous Contributions.

The French Supplement to THE LANCET—under the Editorial Direction of Professor Charles Achar, Professor of Clinical Medicine in the University of Paris; and Dr. Charles Flandin, D.S.O., Chef de Clinique à la Faculté de Paris—has appeared on the dates given in the following list, which sets out the titles and authors of the contributions:—

Sept. 21st, 1918: (1) The Microbic Diversity of the Enteric Fevers, by Professor Achar. (2) Post-Typhoid Atony of the Cæcum, by Maurice Loeper, Professor of the Faculty of Medicine and Physician to the Paris Hospitals.

Oct. 19th, 1918: (1) What the War has Taught Us about Tetanus, by Louis Bazy. (2) Tetanus Consecutive to Superficial Wounds and to Trench Foot: Treatment and Prevention, by Professor Raymond, Médecin Principal de 2me Classe.

Nov. 30th, 1918: (1) General Review of French Cardio-Pathology during the War, by Ch. Laubry, Physician to the Paris Hospitals, Médecin Major de 2me Classe. (2) Methods of Estimating Augmentation in Depth of Volume of Left Ventricle, by Dr. Bordet, Director of the Radiological Laboratory of the Centre of Cardiology of Professor Vaquez, Hôpital St. Antoine.

Jan. 11th, 1919: (1) Gunshot Concussion of the Spinal Cord, by Henri Claude, Professor in the Paris Faculty of Medicine, Physician to the Paris Hospitals; and Jean Lhermitte, formerly Chef de Clinique in the Paris Faculty of Medicine. (2) Contribution to the Study of the Manifestations of Emotional Shock on the Battlefield, by Cl. Vincent, Physician to the Paris Hospitals, formerly Medical Officer to the 46th and 98th R.I. and to the 44th B.C.P.

March 1st, 1919: The Surgical Complications following Exanthematic Typhus, by Dr. Paul Moure and Dr. Etienne Sorrel, Prosecutors to the Faculty of Medicine, Paris, Médecins Aide-Majors de 1er Classe, Surgeons to the French Hospital at Jassy.

April 5th, 1919: (1) Nervous Complications of Exanthematic Typhus, by A. Devaux, formerly Interne of the Paris Hospitals, Médecin-Major de 2me Classe. (2) Note on the Epidemic Diseases Observed in Rumania during the Campaign of 1916-17, by Dr. Henri Vuillet, late Interne of the Paris Hospitals.

May 3rd, 1919: (1) Malaria During the War, by G. Paiseau, Médecin-Major de 2me Classe. (2) Distribution of Soldiers, Temporarily Unfit through Malaria, in Agricultural Colonies, by Professor E. Jeanselme. (3) Studies on Renal Function in Chronic Nephritis, thesis by Pasteur Vallery-Radot, reviewed by Professor Charles Achar.

June 21st, 1919: (1) Recent Work on Cerebro-spinal Fever, by C. Dopter, Professor, Val-de-Grâce, Médecin-Chef to an Infantry Division. (2) Meningococcal Rheumatism and Arthritis, by Dr. Paul Sainton, Physician to the Paris Hospitals.

Aug. 23rd, 1919: Radiological Examination of Pseudoarthroses before and after Operations of Bony Grafts, by Paul Aubourg, Professor Agrégé, Cuneo's Laboratory for Radiology. (Centre for Surgery of Bones, Hospital 75, Cannes.)

Sept. 27th, 1919: (1) Dysidrosis: its Parasitic Nature, by J. Darier, Physician at the Hospital of St. Louis; Member of the Academy of Medicine. (2) The Contagiousness of Favus in Man, by R. Sabouraud.

Nov. 8th, 1919: (1) Secondary Echinococcus, by F. Dévé, Professor at the School of Medicine, Rouen. (2) A Case of Peritoneal Echinococcus, by Charles Flandin, Chef de Clinique Médicale at the Faculty of Medicine in Paris.

Dec. 20th, 1919: French Work on Ictero-Hæmorrhagic Spirochaetosis, by Marcel Garnier, Physician at the Lariboisière Hospital, Paris.

Jan. 31st, 1920: (1) Some Appliances for the Examination of the Nervous and Muscular Systems, by Dr. Jean Camus, Professeur Agrégé of the Medical Faculty in Paris; Médecin des Hôpitaux. (2) The Laws of Tremor, by Dr. Léon Binet, Interne des Hôpitaux, Paris.

Aug. 7th, 1920: (1) Serum Treatment of Hæmophilia, by P. Emile Weil, Physician to the Hôpital Tenon. (2) Coagulation of the Blood: A Study of the Anti-coagulant Action of Sodium Citrate and of the Part Played by Calcium in the Blood. By Marcel Bloch, Chef de Laboratoire in the Faculty of Medicine, Paris.

THE LANCET can be ordered through any Library in France or through the following special agents:—

PARIS.—MASSON ET CIE, 120, Boulevard St. Germain.
EMILE BOUGAULT, 48, Rue des Ecoles.
CH. BOULANGÉ, 14, Rue de l'ancienne Comédie.
FELIX ALCAN, 108, Boulevard St. Germain.
M. CHOISNET, 30, Rue des St. Pères.
H. LE SODIER, 174, Boulevard St. Germain.
MALOINE ET FILS, 27, Rue de l'Ecole de Médecine.
VIGOT FRÈRES, 23, Rue de l'Ecole de Médecine.
MARSEILLES.—TACUSSEL AND LOMBARD, 54, Rue Paradis.
TOULOUSE.—EDOUARD PRIVAT, 14, Rue des Arts.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 18, 1920.

Epidemics of Eastern Europe.

Four years ago, in an introductory note to PRINZING'S "Epidemics resulting from Wars," the director of the Carnegie Endowment (Division of Economics and History) stated that the most serious human cost of war is not the losses on the field, nor even the losses from disease in the armies, but the losses from epidemics disseminated among the civil populations. That truth is being increasingly brought home to us. Dr. L. HADEN GUEST, in the first of the communications regarding his recent observations in Soviet Russia, which appeared in THE LANCET of Sept. 4th, showed clearly that all the facts which had come under his notice confirmed what had been suspected from previous evidence regarding the prevalence of typhus and relapsing fever. During the last two winters the whole of that country has been swept from end to end by these diseases, and all indications point unmistakably to their recurrence on a formidable epidemic scale in Russia during the winter which is now approaching. In our present issue he refers also to cholera, which made its appearance last year in Astrakhan and on the shores of the Caspian Sea. In former years the Volga and other great waterways of European Russia played a conspicuous part in the spread of epidemic cholera through that country and from Russia to Europe. However much credit we may give to the energy and devotion of the medical service which is being maintained by the Government of the Soviets, it is impossible to disregard the consideration that at no time probably in recent history have Russian cities been so vulnerable to this and other epidemic diseases which are carried by polluted water and nourished by every kind of insanitary circumstance. Dr. GUEST'S account of the town of Astrakhan is eloquent in this respect. Nor is the tale of formidable epidemic disease in this part of the world restricted to typhus, relapsing fever, and cholera: small-pox, always endemic in Russia, and now widely prevalent, has also to be reckoned with.

It is a good habit, on hearing of a catastrophe or impending calamity in which one is interested, to ask what is to be done about it. On the purely insular view the United Kingdom is not much concerned. We can keep these diseases out, or round up any occasional imported cases, if our public health service exercises sufficient extra vigilance, and this is certain to be forthcoming. But obviously on this matter Britain cannot afford to be insular. Even if questions of humanity are set aside, and any amelioration of affairs in Soviet Russia by outside action is dismissed as impracticable in present political circumstances, there remains the

feasible and practical policy of effective epidemic prevention by international action in the border States, especially Poland, Lithuania, and Galicia. The case for this policy has often been stated, and it has recently been set out forcibly and eloquently in the letter which Mr. A. J. BALFOUR, on behalf of the Council of the League of Nations, has addressed to the civilised Governments of the world. These border States are the centre of the unsettlement of Europe at the present time; we are now fortunately within sight of peace, which should lead in these lands to that re-establishment of industry and normal conditions of life which, in view of their political and geographical position, is so vital for the whole of the world. The first condition for such settlement to be accomplished is international action, which will strengthen the resources of these States to deal with the epidemic diseases by which, from their relations with Russia, they are perpetually menaced. The most practical question at the moment is the launching of the League of Nations scheme for action in Poland and elsewhere, and with it the direction and coördination of the various offers of help in money and material which have been made by voluntary organisations, including the Red Cross agencies, which are actively engaged in preparing to take their share in the scheme. The developments of this programme are being watched with considerable anxiety by the well-wishers of the League of Nations. The Council of the League have thoroughly explored the position, with the aid of some of the best-known epidemiologists in the world; they have a reasonable and economical programme, and have appointed commissioners, but the actual work cannot proceed until they have obtained money guarantees from the different nations, which so far have not materialised, except in the case of a few countries, including Great Britain and Canada. The future of the matter may well prove, in the parlance of the day, an "acid test" of the reality of the League as a family of nations, ready to act for the common good and to protect members of the family who are threatened by disaster.

Limitation of the spread of these epidemic diseases in the border States seems, in fact, to be the one immediately feasible protective measure which can now be applied with prospects of immediate good result. By the side of it, obviously, should go every effort which, through the League of Nations or by individual sacrifice, can be made to improve the appalling epidemic conditions in Russia itself: a matter in which progress, first and last, must depend on the Government of that country. We are sure that no bona fide appeal from the Soviet Government to the nations of the world for help in organising a sanitary service, such as Dr. GUEST suggests in this week's article, would pass unheeded, and we are equally sure that practical hygienists would be found with the courage and ability necessary to undertake the formidable task involved, if satisfied that they are asked to work for a Government which will not exploit their services for its own ends, but wishes to use and support them for the health of its people. Obviously, however, we cannot at the best expect that measures for prevention of typhus, cholera, or other major epidemics in Soviet Russia can be made really effective in a year or two, so as to influence materially the immediate effect, and the extension beyond Soviet Russia, of the appalling conditions on which Dr. GUEST has supplied us with such recent and valuable evidence.

Varicose Veins.

THE September number of *Medical Science* contains an interesting review of the various methods of treating varicose veins of the lower limbs. The subject has not recently received much attention here, and it is noteworthy that nearly all the authors and papers quoted are of continental origin. This is not owing to lack of material, for the condition is as common in this country as in any other. Probably it is due rather to the fact that hospital accommodation is insufficient to admit of the treatment on a large scale of an ailment which is usually regarded as of minor importance. Yet the total amount of disability and suffering due to varicose veins must be enormous. Patients with this condition can be divided into two main classes: (1) Younger people with bunches of varicosities on the thigh or calf, usually along the course of the internal saphenous vein; (2) elderly people with cedematous legs and one or more intractable varicose ulcers. Patients of the first class are commonly told to wear a crêpe bandage or elastic stocking, neither of which is an efficient palliative. Operations are not in favour because they are believed usually to fail, and this is no doubt true if surgical interference be not exceedingly thorough. The procedure originally recommended by TRENDLENBURG—namely, ligature of the saphenous vein—is not enough. All the tributaries of the vein at the saphenous opening must be ligatured and three inches of vein removed. Even then recurrence may take place owing to the communications on the back of the thigh between the internal and external saphenous vessels. To overcome this an incision should be made over the upper part of the inner head of the gastrocnemius, through which lengths of both veins can be excised together with their communications. This operation can be successfully applied to the less severe cases, but it entails keeping the patient in bed for ten days, in itself a serious drawback. Use has accordingly been made in Germany during the war of a method which, it is claimed, combines efficiency with rapidity. This depends on the injection of a 1 per cent. solution of perchloride of mercury into the lumen of the vein at various points, as a result of which thrombosis takes place almost immediately at the sites of injection. The procedure is painless if care be taken that none of the solution leaks into the subcutaneous tissue, and it is stated that there is no risk from embolism. Should collateral veins become dilated afterwards they can be injected in the same way. Various operative procedures for the severer cases have been devised, several of which depend upon the avulsion of the vein by means of appliances passed along their lumina through incisions at either end, but such methods do not seem to be, surgically speaking, so sound as a thorough excision, even though this has to be rather extensive. The incisions are made, if possible, through sound skin, and, if need be, are extended along the whole length of the leg.

The second class of patients includes the numerous elderly women who display swollen and discoloured legs, week in week out, to despairing house surgeons in the out-patient departments of all large hospitals. With prolonged treatment the ulcers can be made to heal, but the underlying causes—varicose veins and long hours of standing in the course of domestic duties—are still present and the ulcers soon recur. Grafting from the skin at the edges of the ulcer has recently been recommended,

but the artifice does not deal with the underlying cause. A more thorough method involves a spiral incision through the skin down to the deep fascia, beginning at the saphenous opening and ending behind the internal malleolus. The spiral thus consists of two complete turns. The incision must divide even the small transparent veins lying on the fascia and when the bleeding points, which are not numerous, have been ligatured the wound can be sutured. A bandage should be worn for a period after the operation. This procedure has the same objection as most others, that the patient has to remain some days in bed; but there can be no short and easy road to success in so intractable a condition, and the longest cut may prove to be the shortest in the end.

Iatro-Mathematics.

THE whole of the original articles published in a recent number of the principal Swiss medical journal¹ deal with the application of the calculus of probabilities to the elucidation of medical problems. Professor H. ZANGGER, of Zurich, contributes a brief introductory commendation, Dr. H. WEYL discusses some physical applications of the statistical method, Dr. (phil.) E. HAEMIG illustrates the statistical technique of the famous psychologist LIPPS, Professor L. MICHAUD furnishes some applications of the method to clinical data, and Professor ZANGGER concludes with some non-arithmetical examples. To the reader familiar with the writings of V. KRIES, EDGEWORTH, KARL PEARSON, BOREL, and POINCARÉ, the epistemological discussions will not reveal any fresh point of view, while the mathematical or arithmetical technique of LIPPS, not the best available at the time it was devised, has long been superseded by a far more powerful calculus the development of which we chiefly owe to Professor PEARSON and his pupils. This is not, however, to say that the articles do not contain much which all members of our faculty could read with profit and, in any event, the mere fact of publication is significant, for it is probably the first occasion on which an issue of a leading medical journal has been mainly devoted to a discussion of such topics. In this country signs have accumulated that the importance to scientific medicine of the intellectual processes subsumed under such vague headings as Mathematical Statistics or the Theory of Probability are becoming realised by the leaders of the profession. The two departments of State most directly concerned with medical research—the Ministry of Health and the Medical Research Council—employ trained medical statisticians as whole-time officers, and last year the Royal Society of Medicine honoured both statistical science and themselves by conferring the titular Fellowship upon Professor PEARSON. It may not, therefore, be inopportune briefly to indicate reasons why this rapprochement is to be welcomed in the interests of medical knowledge.

If one considers the earliest monument of scientific medicine, the body of writings bearing the name of HIPPOCRATES, the conflict of two opposing intellectual principles is discerned. In the so-called "genuine" works of HIPPOCRATES himself, particularly in the first and third *Epidemics*, and the essay on "Air, Water, and Places," we see

¹ Schweizerische Medizinische Wochenschrift, August 19th, 1920.

employed the principle which has come to be associated with the name of BACON—viz., that of assembling particular instances, of classifying them and using them as a basis of induction. But we also meet with a system of purely deductive reasoning, of inferences drawn from first principles grounded, not upon experience, but upon loose analogies. In the hands of GALEN, who has at least as important a place in the development of medicine as that of ST. PAUL in the evolution of Christianity, the teaching of HIPPOCRATES suffered a transformation. It is true that GALEN, particularly in his doctrine of temperaments, and in the discussion of the factors of what we should call epidemic diseases in his less-known work on the "Differentiæ of Fevers," developed a notation appropriate for the orderly assembling of such data as are specified in the Hippocratic books. But it is also true that he devoted the major part of his labours to a refinement of the strictly deductive method which resulted in the formulation of a quasi-infallible system the influence of which upon the minds of his successors was almost wholly bad. It is of interest to recall that the great mathematical ability of the Greeks was directed to those branches of mathematics which are most remote from the application of quantitative reasoning to aggregates of particulars such as were collected by HIPPOCRATES, that the science of mathematical probability is only a few centuries old. When, after the revival of science, a return was made to the Hippocratic standpoint, pre-eminently by SYDENHAM, it unfortunately happened that the protagonist separated himself from the good as well as from the bad schools of his age. Although SYDENHAM resumed the Hippocratic method and modelled his chief work on the *Epidemics*, he, no more than the Greek physician, grasped the true significance of the quantitative principle. The subsequent history of SYDENHAM'S ideas and of those of an obscure, non-medical contemporary, the London draper JOHN GRAUNT, is full of instruction. Intellectually, there was no comparison between the two men, yet if we inquire whose work conferred more benefit upon medical science, there can be but one answer. That of GRAUNT was far more fruitful; to it we owe, directly, our modern systems of medical and vital statistics, and indirectly, through HALLEY, the scientific development of life assurance. The less learned and less philosophically-minded man realised what the other did not realise—that to draw profit from aggregated particulars they must be quantified and ultimately brought to the test of arithmetic. The historical reason for the slowness of the rapprochement of mathematics and medicine is that the most gifted minds (with rare exceptions such as that of SYDENHAM) were occupied in amending another fault of ancient medicine. GALEN'S specification of the temperamental and procatactic causes of diseases was, and is, of value, while profit can still be drawn from the climatological and meteorological observations of the Greeks. But ancient medicine contributed nothing of value to our intimate knowledge of specific causes. No satisfactory doctrine of *contagium vivum* is older than FRACASTORIUS, and the earlier classification of diseases were symptomatic. Of the simplification and precision, not to speak of the therapeutic and prophylactic advantages, which the researches of experimental pathologists and bacteriologists imported into medicine it is needless to speak. On the other hand, a few able physicians, such as

BORELLI, BELLINI, and BAGLIVI, or our countrymen, FREIND, COLE, and PITCAIRN, who were attracted by mathematical methods, did not pursue mathematical lines which were apt to lead to the discovery of important truths.

The incompleteness of our outfit owing to the neglect of mathematical methods was not a serious practical inconvenience so long as the supply of important discoveries through the use of other tools was abundant. We could not even wish that the great pathological anatomists of the eighteenth and early nineteenth centuries and the great experimental pathologists and bacteriologists of more recent times had devoted themselves to other tasks. But it is becoming every day clearer that the methods they introduced, although of priceless value, are not omnipotent. It is now plain that the most exact specification of the *materies morbi* of such a disease as pulmonary tuberculosis, the most sedulous examination of its channels of entrance to the body and of its extra-corporeal distribution leaves much unexplained. We note the disparate incidence of the disease upon different occupations not subject to specific hazards, wide variations between class and class, and between nation and nation, and recall the words of GALEN, "No cause can be efficient without an aptitude of the body the chief factor in the production of disease is the preparation of the body which will suffer it." But so soon as this aspect is faced, so soon as we envisage the problem of innate or acquired predisposition, the need of the mathematical tool is realised. We enter the region of probability, we have to render an account of a complex of inextricably mingled cause-groups and to deal with average results. Within a narrower circle, that of clinical medicine, the same need arises. Of those infected with the same specific organism, perhaps exhibiting the same physical signs and symptoms, some recover and some die. Or again upon a group of cases ostensibly *in pari materia* the same therapeutic agent exerts different effects. The causes of these divergences are multifold and cannot be submitted to experimental control in isolation. We have a problem comparable to that of the tossing of a penny. The direct evaluation of the force of the throw, of the resistance of the air, of the impact is impossible, we must fall back upon the evaluation of average results and their laws of distribution. The students of molecular physics have for similar reasons had recourse to the methods of mathematical probability, as Dr. WEYL points out, and it is now being appreciated that to medicine a similar application is imperative.

At present the rapprochement of medicine and mathematics is incomplete; our generation will not see many iatro-mathematicians, using better methods and aiming at more attainable ends than the iatro-mathematicians of 200 years ago; mistakes will be made both in choice of method and of material. But the rapprochement will eventually become a firm alliance and lead to the conquest of new territories. For these reasons we welcome the testimony of a changing public opinion rendered by our Swiss contemporary.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At the monthly meeting of the Faculty, held on Sept. 6th, Dr. John Brownlee, director of statistics, Medical Research Council, was admitted as an Honorary Fellow, and Dr. B. W. H. Fergus, of South Africa, was admitted (after examination) as an ordinary Fellow of Faculty.

Annotations.

"No quid nimis."

THE RELIEF OF DISABLEMENT: A DEBT OF HONOUR.

AT the Mansion House last week Dr. Macnamara, Minister of Labour, spoke of the approach to a final stage in the reabsorption of ex-Service men into civil life. Five million fighting men and 200,000 officers have been reinstated, and there remain some 150,000 men who still lack occupation. At least 18,000 of these, Dr. Macnamara said, are disabled. Disability is an elastic term. Scheduled disability, as the medical man knows well, does not cover all the maladjustments to the daily round which prevent a man who has been taken away from his peaceful occupation and exposed to the stress and strain of war from readily returning again into industrial life. Dr. R. Fortescue Fox, in his illuminating letter which appeared in our columns a fortnight ago, adduced even from official utterances a larger total of war disablement than that admitted by Dr. Macnamara at the Mansion House. As a result of his experience at the first treatment and training centre opened in this country Dr. Fox became satisfied that nearly 20 per cent. of the men passing through his hands must be placed in a special category as subnormal, which is to say that while possessing a good capacity for work they are at present unfit for ordinary conditions of industry. Accepting this basis, there must be at least 25,000 of the class in the country. The proportion of subnormal men likely to find their permanent vocation on the land is not very high, the majority having neither the physical strength nor the inclination for agriculture or horticulture. Should land-work alone be provided for men unable to work in towns it will mean that all over the country large numbers will either be doing nothing or going into land-work or town life only to break down and come out again—a cat-and-mouse existence. They are not agriculturists; they cannot be town workers. What is to be done with them?

The problems involved in the provision of permanent employment for disabled men are complex and difficult, demanding for their effective solution sympathetic study from social, economic, and medical standpoints. Medical considerations must loom large in any scheme which is put forward; the debt of honour, in fact, rests heavily on the medical profession, for it alone is in a position to liquidate it completely. The assessment of fitness for work and of the nature and degree of work suitable to the individual, advice and guidance as to the conditions under which occupation is feasible without risk, and even the form of employment most applicable to the particular disablement—these are definitely medical problems. One of the points of reference to the Select Committee on Pensions appointed last May was to inquire into and report upon the position as to employment and training of ex-Service men. White Paper No. 185, recently issued, defines the following classes:—

(1) Men requiring treatment such as would interfere with regular attendance at a continuous course of training on ordinary industrial lines.

(2) Men who are likely to break down or who have broken down in training or employment under ordinary industrial conditions.

(3) Men whose condition necessitates concurrent treatment and training in a convalescent centre.

(4) Men whose disability is such as to make it impossible or undesirable for them to be trained or employed in association with other workmen.

Some medical men may find an administrative classification such as this not very easy to interpret, and apparently the Select Committee recognised the difficulty, for it points out that concurrent treatment and training may be given either in convalescent centres or in orthopaedic, neurasthenic, and other hospitals, where classification can then be carried out. But the accommodation at present available is still lamentably insufficient, and the provision of further accommodation is urgently recommended by the Select Com-

mittee, which regards such centres for treatment and training as of the greatest value if established on efficient and practical lines.

Only those who have been closely in touch with work among military convalescents can have any idea of its many-sidedness. In the current issue of the *Journal of the R.A.M.C.* Dr. L. Graham Brown shows that the convalescent dépôt in France meant something more than re-creation or recuperation of the disabled man's physical powers; it meant what is of equal, if not greater, importance—the re-creation of his mental and moral character by placing him in an environment where spiritual influences can work their effect. Those to whom this may seem a large claim should study the rapid and inevitable deterioration seen in the disabled man who is not promptly re-absorbed into communal life. The streets of London and of other large cities in this country, and doubtless of other countries, are full of deplorable saprophytes, who are not likely to get less numerous as time goes on. Dr. Brown, whilst not undervaluing the influence of chaplains, of the Y.M.C.A., or of lectures by commandants, ascribes the curative atmosphere of the dépôt chiefly to the competitive spirit built up throughout the whole work and play of the dépôt by the officers in charge of it. Nothing has been shown, or is now likely to be shown, able to take the place of communal life lived at the highest level applicable to the particular disablement. An analogy may not unfairly be drawn with the admitted success of communities, many of them now long established, where the impairment is of a different character. Every county mental hospital forms a self-supporting and self-governing State to a degree which needs to be seen to be realised. Some colonies of mental subnormals make their own bread, grow their own wheat, manufacture their own ice for refrigerators in which is stored meat derived from their own farm. The hospital farm includes cattle, poultry, pigs, orchard, kitchen and flower gardens, all cared for by patients under expert supervision. There are shops for carpenters, for plumbers, for cobblers, for tailors, and many others. The hospital chapel is the size of a small village church, and a large theatre, dancing- and billiard-rooms, playing-fields, and tennis-courts complete the arrangements for recreation. The cases are not quite parallel, for in the disabled community provision must be abundantly made for wives and children, but nevertheless the county mental hospital might suggest the nucleus of a permanent centre for war disablement. The problems in each case are essentially medical, and the administrator requires a medical training in addition to his other gifts. Since it is quite impossible to assess a man's capacity for work under outside conditions before he has been trained or tried, admissions to such an institution would include a majority of men who would subsequently be able to leave and fill their place in ordinary life. The colony would retain as permanent inmates the second of the four classes mentioned in the White Paper.

THE CARE OF MENTAL DISEASE IN SCOTLAND.

WE learn from the sixth annual report of the General Board of Control for Scotland that on Jan. 1st, 1920, there were 17,432 patients on the Board's register, while on Jan. 1st, 1916, there were 18,842 patients, showing a fall of 1410. Between 1916 and 1917 there was a decrease of 181; between 1917 and 1918 a decrease of 536; between 1918 and 1919 a decrease of 524; and between 1919 and 1920 a decrease of 169. This last figure perhaps serves as an indication that the influences which produced a marked decline, especially in the number of pauper lunatics during the period of the war, are beginning to subside. The total number of patients admitted to establishments (excluding transferred patients) during 1919 was 3619, which is 226 more than in the previous year, 482 more than in 1917, 184 more than in 1916, 12 less than in 1915, and 63 more than the average for the quinquenniad 1910-14. Of private patients there were discharged recovered during 1919, 318, which is 66 more than the number in the preceding year and 105 above the average

of the five years 1910-14. The number of pauper patients discharged recovered was 955, which is 145 more than in the preceding year and 178 less than the average for the five years 1910-14. The number of private patients discharged unrecovered, excluding those transferred during 1919, was 187, which is 45 more than last year and 56 more than the average of the five years 1910-14. The number of pauper patients discharged unrecovered was 282, which is 26 less than the number so discharged in the preceding year, and is 97 less than the average for the five years 1910-14. The number of private patients who died during 1920 was 314, which is 36 less than in 1918 and 130 more than the average of the five years 1910-14. The number of pauper patients who died was 1522, which is 374 less than in 1918 and 258 above the average of the five years 1910-14. There is a somewhat remarkable fall in the admission to care in private dwellings under the boarding-out system obtaining in Scotland. The Board of Control attributes this to the general decrease in the number of pauper lunatics, to the disorganisation in the arrangements for placing patients caused by the war, to the improved financial condition of many of those who formerly received patients, and to the lack of housing accommodation. The cost of maintenance of patients per head is shown by the following interesting figures. In asylums the average weekly cost was 14s. 7d.; in the licensed wards of poor-houses, 13s. 8d.; and in private dwellings, 9s. 7d.

PRIMARY ACTINOMYCOSIS OF THE TONGUE.

PRIMARY actinomyces of the tongue is fairly common in cattle, but is an infrequent occurrence in the human subject. Professor R. Kockel,¹ of Leipzig, records a case in a man aged 40, from whose tongue a hard superficial tumour, the size of a bean, had been removed. On microscopical examination the tumour at first sight resembled a rapidly growing sarcoma, as it consisted of a tissue rich in cells which had penetrated between the muscle fibres of the tongue causing pressure atrophy; but after serial sections had been made a central purulent focus was discovered in the middle of which a small foreign body was seen which was apparently a piece of wood surrounded by actinomycotic granules. The explanation given of the localisation of the lesion is that the patient, in order to break himself of the practice of excessive cigarette smoking, had been in the habit of chewing a wooden tooth-pick, a piece of which in all probability had become broken off and penetrated the tongue. Professor Kockel remarks that the case is of interest because wooden tooth-picks, like matches, have hitherto enjoyed the reputation of being germ-free. The case also shows that actinomyces of the tongue in man, as in cattle, may appear in the form of a relatively benign new growth and does not always show a tendency to rapid dissemination.

THE PROBLEM OF DENTAL DISEASE.

IN the *British Dental Journal* for August 16th Dr. James Wheatley, the county medical officer of health for Shropshire, makes a valuable contribution to the subject of dental caries. Dr. W. E. N. Dunn called attention to this article in a letter last week (p. 576). For several years Dr. Wheatley has been giving, in his yearly reports, data with regard to the incidence of caries in the area under his supervision. The figures he has now furnished are based on the examination of 37,527 children before the war and 10,593 children since the war. These figures show remarkable improvement in children now at the age-period of 5 years; before the war only 5 per cent. of the children in this age-group were free from caries, whereas no less than 44.4 per cent. of post-war children showed no decay. This great improvement he attributes largely to the restriction and modification of food during the war as it affected especially sugar, bread, and milk. Children of 5 have, of course, grown up into these conditions. In the

case of sugar the consumption was lessened and sweets almost disappeared for a period. The bread was modified by the addition of so-called offal to the flour and by the prohibition of the sale of new bread. This, together with the necessity of eating crusts owing to the shortness of supply in general, led to an increase in the practice of mastication. In a small measure Dr. Wheatley considers the improvement may be due to the campaign he started against dental caries, but the chief point of interest is the confirmation by figures of the belief that the cause of caries lies in the food and not in assumed constitutional conditions. In dental caries, Dr. Wheatley remarks:—

"We are dealing not with a disease which we might alleviate or to some extent prevent, but with a most powerful cause of disease and with a condition which is liable to aggravate every other disease. We have an opportunity of removing a cause of disease such as does not present itself in any other branch of preventive medicine."

A national scheme for the prevention of dental caries is badly needed, and there is already a sufficient basis of unanimity on essentials for such a scheme to be a success; but if it is to yield the quickest and best results it requires the whole-hearted coöperation of the medical profession.

THE FRACTIONAL TEST-MEAL IN RELATION TO GASTRIC FUNCTION

THE use of a test-meal for the diagnosis of gastric diseases is well known, and considerable interest, at times lighting up into controversy, has been aroused over this subject. There is little doubt that the Ewald test-meal, consisting as it does of a pint of weak tea and 2 oz. of toast, provides a useful medium for the analysis of the gastric contents, removed one hour after the meal has been consumed. The methods of analysis are capable of yielding accurate results, but it is obvious that our interpretation of such results is at fault. There are so many factors concerned in the secretion of gastric juice—viz., (a) nervous control; (b) blood-supply; (c) alteration in the secretory cells lining the stomach; (d) pyloric sphincter control over the emptying of the stomach—and these are not taken into consideration. This applies more especially to the Ewald test-meal, as we have a single analysis at the end of an hour's stay in the stomach on which to base our conclusions. Rehfuß¹ in 1914 devised a method of obtaining small quantities of the gastric contents at given intervals, thus enabling us to follow the whole course of digestion of a test-meal, and the variations met with both in health and disease. The method has received considerable attention in America, if one may judge from the numerous publications made by Rehfuß and his co-workers. Dr. C. M. Wilson alluded last week to the investigations at the Johns Hopkins gastro-intestinal clinic under Dr. T. R. Brown. The results of the application of this method of investigation of gastric function are far-reaching, and the method promises to become universal. It is simple to apply, and less unpleasant to the patient than the large stomach-tube and evacuator.

The use of the fractional test-meal has demonstrated very forcibly the fact that hyperchlorhydria is not such a definite pathological condition as we have been led to assume in the past. A large number of normal individuals show quite as definite a hyperchlorhydria as was previously considered to be pathological, and this gastric response applies to all varieties of foodstuffs. The discussions which followed papers read before the annual gathering of the American Therapeutic Society in May last fully emphasised this finding. It is quite clear from the observations made at this meeting that no one was able clearly to define hyperchlorhydria. Each individual varies in his gastric response to food, and the gastric mucosa may secrete an excessive amount of hydrochloric acid without any symptoms of hyperacidity. Dr. Julius Friedenwald, in discussing the treatment of hyperchlorhydria, considered that four ætiological factors were concerned in its production, and until the cause was discovered no proper

¹ Münchener medizinische Wochenschrift, Sept. 3rd, 1920.

¹ Rehfuß and Hawk: Jour. Amer. Med. Assn., 1914, lxiii., 11.

therapeutic measures could be instituted. The four aetiological factors were:—

1. Primary disturbance of the gastro-intestinal tract—e.g., ulcer, pyloric obstruction, acid gastritis, atony, and chronic constipation.
2. Constitutional and organic diseases—e.g., cholelithiasis, nephrolithiasis, chronic appendicitis, chlorosis, cerebrospinal lesions, abdominal adhesions, and genito-urinary infections.
3. Nervous affections—e.g., mental strain, overwork, worry, neurasthenia, hysteria, and mental conditions.
4. Disturbances of the endocrine glands.

Dr. W. Wayne Babcock advocated the operation of cholecystogastrostomy to relieve cases of hyperchlorhydria, especially in those where the use of therapeutic measures have not given permanent relief. He considers that the pyloric area of the stomach suffers most from the irritation of the acid gastric juice and that the introduction of bile into this area relieves the irritation and prevents the formation of peptic ulcers. Dr. Rehfuß, in the discussion which followed, outlined his views, which were based on the results of his method of analysis of the gastric functions. The presence of hyperchlorhydria in people with no symptoms, and as high as that found in pathological cases, showed conclusively that it was not the quantity of acid which accounted for the symptomatology of this condition. On this account he could not conceive that direct communication between the gall-bladder and the stomach would benefit hyperchlorhydria. Reyfuß and Hawk² have recently summarised the results of their work on this subject. They have obtained a vast amount of experimental data, particularly as regards the normal gastric output both during gastric activity and rest. The variations met with in health must be clearly defined before any interpretation is placed upon the gastric analysis in disease. Besides the fact already noted that a number of normal individuals show a hypersecretory response to all classes of foodstuffs, they find that there are both fast and slow responses in the normal individual. The curve of gastric secretion is made up of psychic and chemical secretions, and by means of the new method these can be separately determined as well as the secretion in the fasting stomach, and also the amount of duodenal regurgitation. For an analysis of gastric function they use the Ewald test-meal, and divide the gastric responses met with in disease into four groups.

1. Clean digestion, showing simple secretory variations.
2. Secretory variations plus gastric mucus, indicating inflammation of the mucous membrane.
3. Secretory variations plus blood (intragastric) indicating ulceration of the mucous membrane.
4. Secretory variations plus blood, pus, mucus, and bacteria, indicating ulceration and infection of the mucous membrane.

They conclude that there is no specific curve in any gastric condition, and all that can be said is that disease may produce definite types of secretory and motor alterations.

Dr. J. A. Ryle's paper, published in THE LANCET of Sept. 4th on the investigation of gastric function, embodies a considerable amount of work on normal individuals, and represents a laudable attempt to analyse the factors concerned in gastric secretion. Hitherto this method of the fractional test-meal has not been taken up in this country, and we hope that Dr. Ryle's paper will receive the attention it deserves. He fully confirms the work of Rehfuß and others, and is able to give further information. The effect of different types of meal on the secretory curve is well shown in the curves, and demonstrates very clearly that in this method we have a ready means of studying the normal physiology of the stomach. A comparison of these curves with those found in pathological conditions is instructive, particularly the high acidity of the resting juice, the steep curve, and the continued secretion in the duodenal case (Chart 4). The method would appear to have almost unlimited applications, both in physiology and clinical medicine. Not only can we estimate the responses from the point of view of

motility of the stomach, but the time relations of pain and other symptoms can be determined, also the local effects of drugs. The presence of pathological elements can be readily detected, and the presence of regurgitation of intestinal contents at the end of gastric digestion. The method, therefore, provides abundant data for the logical interpretation of gastric analysis. Further research is needed, especially upon the factors which produce alterations of function, as well as the appearance of certain pathological elements. The fact that carcinoma of the stomach in its early stages gives rise to very little disturbance of function emphasises the importance of such investigations.

NEUROBLASTOMA SYMPATHICUM.

Dr. P. C. Gunby,¹ of Rochester, Minnesota, records an example of this rare condition, the clinical diagnosis of which was confirmed by post-mortem examination. The patient was a boy, aged 13 years, who was brought to the Mayo Clinic for relief of failing vision, weakness, and small tumours of the scalp, which had first appeared six months previously. Examination showed a well-developed boy, moderately emaciated, whose skin was very pale with a slight greenish tint. The entire forehead and vertex were studded with nodules varying in diameter from 2 cm. to 6 cm. Moderate bilateral exophthalmos was present. A smooth mass was felt in the left hypochondrium. Ophthalmoscopy revealed bilateral choked disc, and a skiagram of the skull showed a diffuse porosity suggesting the osteoclastic type of bone malignancy. On the strength of these findings Dr. Gunby made a diagnosis of neuroblastoma sympathicum, probably primary in the left suprarenal. On the other hand, the possibility of hereditary syphilis was considered owing to the presence of papules and scarring about the body, a maternal history of miscarriages, scarring about the uvula and fauces, and slight roughening of the tibiae. Anti-syphilitic treatment was instituted, but death took place about two months after admission to hospital without much change in the child's condition. The autopsy showed a large growth resembling malignant hypernephroma of the left adrenal, numerous metastases in the bones of the skull, sternum, vertebrae, ribs, and lateral lumbar and retro-aortic lymph nodes, very extensive tumour rarefaction and softening of the skull bones, hypostatic broncho-pneumonia, marked hyperemia and hyperplasia of the spleen. There were no metastases in any of the parenchymatous organs. Microscopical examination of the adrenal tumour and of the metastatic nodules showed none of the characteristics of hypernephroma, but the tumour cells, tangled masses of fibrils, and rosette formation associated with neuroblastoma sympathicum were present.

STERILISATION OF PRIMARY SYPHILIS.

In a recent issue of the *Bulletin de la Société Française de Dermatologie et de Syphilographie* an account is given by Dr. Jean Gouin and Dr. L. Leblanc of the serological reactions of cases of primary syphilis undergoing intensive treatment. The writers have found that in the great majority of cases of primary syphilis with a negative Wassermann reaction (W.R.) the blood becomes positive during the course of the initial intensive treatment. This phenomenon the authors term "activation sérologique," analogous to the "réactivation de Milian" or provocative W.R. of latent syphilis. Fifteen cases of primary sore were observed. Of these 12 gave a completely negative serum reaction and 3 a partially negative one. During the course of intensive treatment a positive W.R. was obtained in all of the 12 except one. When a weak reaction was obtainable at the beginning of the course a strong positive was subsequently observed. Treatment consisted of weekly injections of novarsenobenzol up to a total of 4 to 6 g. The W.R. was performed before every injection, and sometimes twice between injections. In some cases mercury was given in addition to

² Reyfuß and Hawk. Jour. Amer. Med. Assn., 1920, lxxv., 449.

¹ American Journal of Medical Sciences, August, 1920.

arsenobenzol. With regard to the period at which a positive Wassermann reaction was obtained the observations of these writers are in line with those of Levy-Bing and Gerbay. The serum reaction almost always became positive from 40 to 45 days after the infecting coitus. Too much stress is, as a rule, placed on the age of the chancre and too little account taken of the period of incubation. To obtain a truer valuation these two periods should be added together. Out of Dr. Gouin and Dr. Leblanc's observations several points of interest arise. If, in spite of the initiation of treatment at an early stage of syphilis, a positive reaction is nevertheless obtained during the course of treatment, is it legitimate to consider that we have sterilised that case? That being so, is it not desirable that repeated W.R.'s should be made during the course of treatment of every case of primary syphilis? If the serum reaction remains negative throughout, as it did in 1 out of the 15 cases mentioned, it is legitimate to regard such a case as sterilised. If, on the other hand, at any period after the starting of treatment the phenomenon of "activation sérologique" is observed the case must be regarded as one of secondary syphilis, regarded from the point of view of future treatment. The work of Dr. Gouin and Dr. Leblanc certainly suggests that fewer cases of primary syphilis are completely sterilised by early treatment than has been generally supposed.

BENZYL BENZOATE IN WHOOPING-COUGH.

IN a number of important communications Dr. David I. Macht has reported the results of investigations made at the Pharmacological Laboratory of the Johns Hopkins University, which show an interesting relation between the chemical structure of the principal opium alkaloids and their action on smooth muscle. They can be divided sharply into two groups: the pyridin-phenanthrene, of which morphine is the principal member, and the benzyl-isoquinolin, of which papaverin is the principal. The morphine group is characterised by a stimulating action on smooth muscle, increasing its contractions and raising its tonus, while the papaverin has a sedative effect, inhibiting contractions and lowering tonus. Pharmacodynamic analysis of the papaverin effect points to the benzyl nucleus of the papaverin molecule as responsible for the sedation. Dr. Macht then searched for a simpler compound of the benzyl with the sedative effect of papaverin on smooth muscle and without its narcotic effect. He found that benzyl benzoate had all the effects of papaverin on smooth muscle and was much less toxic. The therapeutic applications naturally followed. The drug was tried in excessive intestinal peristalsis, pylorospasm, uterine spasm, spasm of the gall-bladder or urinary bladder, ureteral spasm, angiospasm, and other conditions, and found effective. In our issue of Sept. 4th (p. 512) we summarised another paper, by Dr. Macht, dealing with the effects of benzyl benzoate in hiccup. The drug was also found valuable in bronchial asthma. By a fallacious process of reasoning it was used in spasmodic conditions of the larynx, such as whooping-cough, in which the muscles involved are not smooth but striated. However, as according to some authorities whooping-cough is accompanied by more or less bronchial spasm, and Dr. Macht had noted some slight sedative effect in cough, he tried it. The results, which he reports in the Johns Hopkins Hospital Bulletin for July, were unexpectedly gratifying. All other medication was discontinued and a 20 per cent. alcoholic solution was given by mouth. The dose varied from 5 to 40 drops in water three or four times a day, according to age and severity of the disease. For young patients it was flavoured with a few drops of benzaldehyde and given in sugar, water, or milk. It was soon found that the addition of benzaldehyde, in amounts varying from 1 to 5 per cent., made the mixture more effective. About 90 per cent. of the patients showed more or less beneficial effects, and about 50 per cent. marked improvement. The effects were not curative but palliative—reduction in the violence or number of the paroxysms, or both, and elimination of such sequelæ of violent spasms as vomiting, subconjunctival hæmorrhages, lack of sleep,

and emaciation. In many cases the relief was so marked that the parents came begging for more of the drug. Many of the patients who responded favourably to the drug had been treated unsuccessfully with bromides, antipyrin, quinine, belladonna, paregoric, and even heroin. In some cases, including three of Dr. Macht's own children, the benzyl was alternated with other treatment, none of which, excepting heroin in toxic doses, proved in the least effective. On the other hand, the benzyl benzoate with benzaldehyde gave remarkable relief both to violence and the number of the paroxysms. There was no evidence that the treatment influenced the duration of the disease. Dr. Macht then investigated the question, How does benzyl benzoate act in whooping-cough. In the first place, the anti-spasmodic effect on bronchial spasm probably plays some rôle. Secondly, he conducted experiments in regard to the action on striated muscle and found a sedative effect, but less than on smooth muscle. Thirdly—a fact of great importance—he observed a slight anæsthetic effect on the larynx. He also found that the anæsthetic action which he had shown to be marked for benzyl alcohol is exhibited in high degree by benzaldehyde, and to a lesser degree by benzyl benzoate, and that both the latter when taken by mouth are excreted in the saliva and bronchial excretions. They therefore probably diminish the sensitiveness of the irritable mucosa of the larynx, and so prevent the reflex which starts the spasms. Fourthly, he found that the benzyl esters are expectorants, and therefore probably help to liquefy the tenacious mucus which is found in the larynx in whooping-cough. Fifthly, he found that benzyl benzoate is sedative to the respiratory centre. Lastly, it was possible that the antiseptic properties of benzyl esters might play a rôle. The low toxicity of benzyl benzoate is important, and would allow administration in larger doses than those recommended.

THE LIPOID GLAND.

IT has been recognised for some time that there are two varieties of adipose tissue: the familiar subcutaneous form, and another in which the fat occurs as small discrete droplets in cells grouped together in well-defined masses. Histogenetically these types of adipose tissue appear to be distinct, and observations on the hibernating glands of such animals as the hedgehog, and the interscapular glands in cretins, both consisting of this glandular fat, show that physiologically they are also different. In a valuable contribution to the current number of the *British Journal of Experimental Pathology* Dr. W. Cramer carries the matter a step further. He points out that in the embryos of all the mammalian species that have been studied a form of adipose tissue exists in which the cells, arranged in lobules, are rich in protoplasm and contain droplets of fat around a central nucleus. In most adult animals this tissue loses its distinctive appearance and is seldom recognisable macroscopically. In the rat and the mouse, however, the embryonic form persists throughout adult life, and can be distinguished very easily as sharply defined, reddish-brown masses. Typical glandular fat differs from ordinary adipose tissue in that its cells are rich in lipoids and contain a relatively large amount of protoplasm. But these differences are relative rather than specific, for the ordinary isotropic fat contains a varying proportion of anisotropic lipoids, while the glandular tissue may contain much true fat, with an apparent consequent loss of protoplasm. The essential difference, however, is brought out in fasting or overfed animals. When food is withheld from a rat or mouse the ordinary adipose tissue becomes greatly diminished in amount, but the glandular fat shows no obvious decrease. Conversely, in states of obesity the glandular fat shows hardly any increase. Still more striking are the results obtained by feeding animals on a diet free from all vitamins. In these circumstances the animals become extremely emaciated, and the glandular fat loses its lipid contents. But it still remains as a tissue; its cells are large, rich in protoplasm and mitochondria, and are surrounded by capillary blood-vessels: it has, in fact, the characters

which one associates with an organ of internal secretion. Dr. Cramer brings forward a certain amount of evidence to show that glandular fat is functionally related to the thyroid and adrenal glands, and that it contains a reserve supply of a vitamine which can be drawn upon when this substance is absent from the diet. He suggests that this tissue should be known as the lipid or cholesterol gland. The subject is obviously one of great interest, and offers a fruitful field for inquiry.

AN ARTIFICE IN ABDOMINAL PALPATION.

PALPATION of the abdomen remains in many instances a crux for the present-day clinician. The numerous artifices suggested to render it more easy and overcome the contractions of the abdominal muscles and distension of the walls, besides trying our patience to the utmost, frequently fail us. But palpation is always the most valuable method of exploring the abdomen and the starting-point of all secondary and subsidiary investigations. Professor M. Ascoli,¹ of the University of Catania, has devised a simple method which he has found very helpful and which is, perhaps, not sufficiently well known. The manœuvre consists in this: to ask the patient, who is lying in a supine position with the head and shoulders slightly raised, to take hold of both ankles with his hands and forcibly drag them up, keeping the legs flexed on the thighs and the thighs wide apart and more or less completely flexed on the abdomen. By this means, owing to the discomfort of the patient's position, the consequent distraction of his attention and the force exercised by other groups of muscles, which can be increased by directing him to squeeze his heels, a complete relaxation of the abdominal musculature and flaccidity of the walls can be easily obtained. It must be understood that this artifice is neither universal nor infallible any more than any other, but it certainly deserves trial. In this position the examination is made by introducing one forearm between the patient's legs, while the other takes a lateral position, and when concentrating the palpation on any particular part the patient is asked to increase for a moment the flexion of the thighs. Nearly all methods of palpation can be applied in this position, including that of Hausmann. The method is simple and inoffensive to the patient when the pubic region is covered with a towel.

THE AIR WE BREATHE.

THERE is a wealth of material in the second report just issued on "The Science of Ventilation and Open Air Treatment"² by the Medical Research Council from the pen of Leonard Hill, M.B., F.R.S., the director of the department of Applied Physiology to the Council. We dealt with Dr. Hill's first report in THE LANCET of Sept. 20th, 1919. A comprehensive and up-to-date treatment of the subject is again presented which will be read with profit by all those who have the question of healthy environment at heart. We begin to see from this report how antiquated were our ideas, amongst other things, of ventilation, artificial heating and lighting, and Dr. Hill's demonstration of the value of air in movement must bring conviction to the minds of sensible folk. The chemistry of the air is one thing, the physics of the air is another. Carbonic acid is a bogey, humidity and temperature are vital factors. The old rule laid down by Pettenkofer in 1860 and taught by sanitarians for 60 years, that the percentage of CO₂ is a rough indicator of the purity (or adaptability for respiratory purposes) of the atmosphere must go. Water (or humidity), with stagnation, is a greater poison than CO₂, simply by checking the function of that great organ, the skin. Apart from respiratory demands the environment should be such that the skin has freedom of action and a stimulus given to it by a constant flow of fresh air. This fact reminds us of the work of experimental diffusion in the

physiological laboratory. As is well-known, the best and most complete results of carrying away the diffusible substance are obtained by keeping up a constant stream of water on the external side of the membrane. So with the respiratory and skin functions. Dr. Hill brings out these points vividly at the same time as he deals exhaustively with the subject in general. He commences with a dissertation on the phenomena of radiation, which is succeeded by a consideration of the penetration and action of light on living organisms. He next deals with the colour of the skin and racial adaptation to climate, passing on naturally to the emission, absorption, and reflection of light by white and black skin. Later he discusses in very interesting sections the influence of sunlight on the transpiration of wet black and white surfaces, with its practical bearing on the question of correct clothing. Heatstroke, food, and exercise conclude the first section. In Section II. we come to the chemical purity of the atmosphere in crowded confined places and in mines, the smoke nuisance, dust, heat stagnation and fitness, health and environment, the physics of clothing, fever, open-air treatment, and methods of ventilation and heating. The whole is a practical study of the common obstacles to the practice of health and the simple way out. It is scientific common sense all the way.

THE FIRST REPORT OF THE MINISTRY OF HEALTH.

THE Ministry of Health Act received Royal assent on June 3rd, 1919, its principal object being to concentrate the main health services of the country in a single department under a Minister of Health responsible to Parliament. Dr. Addison, the first Minister, has just issued the first instalment¹ of his first annual report, dealing in three sections with public health, local administration, and local taxation. The first year in such a reshuffling as was involved in the inauguration of a Health Ministry is naturally a period of reconstruction, for, in addition to its initial commitments, which were immense, the Ministry has during the year taken over from the Board of Education the medical inspection and treatment of school children, from the Home Office its powers under the Anatomy Acts, and other powers and duties in relation to lunacy and mental deficiency. Sanguine people may feel some disappointment that the promised outline of a comprehensive policy for the extension and development of health services has not yet been submitted to Parliament, and that the fate of the Poor-law still hangs in the balance. Dr. Addison explains in his prefatory note how the magnitude and complexity of the issues involved have combined with the heavy Parliamentary pressure in preventing the presentation of this policy as a whole. The broader work of the Ministry of Health still remains to be done. The present report is a chronicle of such developments and extensions of health work as could properly be set on foot without fresh legislation; important indeed, but of less burning interest than what is to come. The Minister of Health records his appreciation of the cordial coöperation in many spheres of action which he has received from authorities locally responsible throughout the country. It is on the continuance and further development of this coöperation that the success of the larger measures will chiefly depend. The coming year will doubtless be the arena of a bold attack on the larger issues. The annual report for 1919-1920 of the chief medical officer of the Ministry is announced to appear shortly in a separate volume.

THE Neurological Section of the Royal Society of Medicine has invited Dr. Henry Head, F.R.S., to deliver the Hughlings Jackson lecture, and it will be given at 1, Wimpole-street, London, W., on Oct. 7th, at 8.45 P.M. The subject of the lecture will be "A New Conception of Aphasia."

PUBLIC HEALTH IN SOVIET RUSSIA.

By L. HADEN GUEST, M.C., M.R.C.S. ENG., L.C.C.
SECRETARY AND PHYSICIAN TO THE BRITISH LABOUR DELEGATION.

III.—ASTRAKHAN AS A CENTRE OF INFECTION.

THE unfortunate illness of a member of the delegation made it necessary for him to remain on board the s.s. *Bielinski* when we arrived at Saratoff, and as I could not leave him my journey on the Volga was extended right down to Astrakhan. Two other members of the party—Mrs. Snowden, a member of the delegation, and Mr. Bertrand Russell, who came with us—remained on the steamer with me to nurse the patient. During this voyage we lived with Mr. B. M. Sverdlov and his staff, and without the official receptions, speeches, and parades which had been our lot up to that time.

Lack of Antimalarial Measures.

On approaching Astrakhan I was struck by the complete absence of all measures to prevent malarial infection. The fact that I insisted on fitting up the invalid's cabin windows with mosquito muslin was evidently a revolutionary proposal—copied, by the way, by all the staff who could obtain the very scarce material. Conversation on this subject led Mr. Sverdlov to ask me to undertake an inspection of Astrakhan and report to him on the hygienic measures necessary to prevent malaria and improve health conditions generally. I accepted this suggestion after some demur (on the ground of poaching on the Russian doctors' preserves) for two reasons: (1) the wish to assist in any way I could with suggestions for improving the demonstrably lamentable conditions, and (2) the desire to see for myself the actual conditions from the medical inspector's rather than the medical tourist's point of view. On arriving at Astrakhan I had a conference with the chief medical officer of the town, Dr. Mishkin, and his assistants, Drs. Sandler and Saccal, and got from them a great deal of general and also of precise information in answer to a questionnaire which I had previously drawn up. On June 6th I made an inspection of the town in general, including the surroundings, the two large rubbish deposit areas, and the hospitals. On June 7th I inspected the waterworks and some other parts of the town. I was informed that Astrakhan had only recently come under civilian control, having been up to about three weeks previously in the hands of the Red Navy, who, I was told, had done pretty well what they thought fit.

General Sanitary Condition of the Town.

The town contains about 200,000 inhabitants, and is built on the delta of the Volga on marshes, and surrounded by marshes. Ferry steamers—which were busy and crowded—are necessary to connect parts of the town which are separated by arms of the river. At the time of our visit the temperature was over 120° Fahrenheit in the shade, and the place extremely oppressive. The streets themselves are very dirty. No water carriage system for sewage exists, and the sanitary service of refuse-collecting carts for the conveyance of rubbish and faeces to the dumping grounds outside the town has been suspended for over a year. In many streets there were long continuous heaps of refuse and faeces, about 2 ft. high, dried into a compact mass all the way down the middle of the roadway. Very many houses had been partly destroyed by severe aeroplane bombing, and in one street practically every house was gutted, the outer walls alone standing. The dump-grounds for refuse had been untouched for about a year and were deserts of drifting dust. The waterworks was in such a state of disrepair that the pumping-engines spouted water from the joints of the machinery at each stroke, and the large iron store-tanks had to be plugged with match-like bits of wood wherever the water pressure broke through their thin crust, and the sand filter was simply not working. The sand filter also leaked into the road—a very broad although squalid avenue—in front of the works, and formed a little lake about an

acre in extent. Nevertheless, the water-supply to the town is still maintained, and the engineer in charge (a man with the typical appearance of chronic malaria) was of opinion that the water in the pipes was purer than that in the Volga. It was less discoloured, but the filter was quite useless against bacteria. Another defect of the waterworks is that its intake was in the region of the Astrakhan docks in the Volga, about 50 yards from the bank, and, on the day of my visit, immediately behind the stern of a steamer apparently engaged in trade with Baku in the Caspian.

Mosquito-breeding Grounds.

Not only are the streets dirty, but pools of water are common everywhere—at the roadside, in the gutters, on bits of waste land where holes have been excavated, in the middle of the road, and, in fact, everywhere where a depression in the ground exists. One of the first things to attract my attention on leaving the boat and walking out of the dock gates was a little stagnantly moving gutter stream covered with a green water weed into which a large bright-eyed frog plopped on my approach. This little gutter stream meandered out from under a wooden paling higher up the road and no doubt went on to the Volga. In many of the narrow by streets there were large pools in the road. The basements of the gutted houses previously referred to were flooded with water. Round the town are wide expanses of shallow water covered with picturesque whispering reeds—6 to 10 feet high—with little creeks creeping up to the house walls and winding into the town itself. On going into the matter in detail with Dr. Mishkin and his assistants I found that seven-tenths of the area of the town is water surface. When I asked what was being done about the flooded basements, the pools in the streets, the gutters, and the accumulation of water on waste land in the town, I was told that it would dry up later on in the year. Meanwhile nothing was done. When I inquired what was being done about the picturesque lagoons of reed-shaded waters creeping right up to the town I was told they were too extensive to tackle. It was a case of "Nitchivo" (Never mind)—a universally employed Russian expression embodying the spirit of that passive non-resistant acceptance of adverse conditions of hardship and evil which is characteristic of Russian people.

Universality of Malaria.

Under these conditions I was not surprised to learn that malaria is universal and distributed over all sections of the population. Fishermen, who live in extremely picturesque wooden shanties on the edge of the river or on islands only an inch or two raised above its surface, suffer most. The population on a little hill—or rather mound—in the centre of the town on which the local fortress (Kremlin) is built suffer least. The outskirts of the town are more affected than the centre. When I pressed the importance of these facts and asked why at least drainage of pools and stagnant water in the town itself was not carried out, I was told that it had been discussed, but that there was a lack of labour and materials. Both of these statements were true in general, but nevertheless it was possible to get labourers from Persia for the docks (Mr. Sverdlov arranged this while we were in Astrakhan), and a good deal might have been done with no more implements than a few shovels and picks.

When I suggested that there was an unlimited supply of oil available at Baku (connected by railway and steamer lines) for spreading over pools, I was told that this was not done for fear of killing breeding fish and injuring the fish industry and caviare industry of Astrakhan. But however valid this reason might have been for certain water areas, it did not apply to the mosquito-breeding grounds immediately round and in the town, which were mere stagnant pools or waste expanses of water. The treatment of malaria in Astrakhan was no more satisfactory than the prevention. There was no attempt at the isolation of cases, no material for isolation, and a practically complete absence of quinine. I did not have time to examine individual cases at Astrakhan, but I did so at Saratoff, where I saw two malaria cases untreated with quinine

with spleens extending to below the umbilicus, a condition I was assured was common. Most of the cases of malaria in Astrakhan are said to be benign, but there had been ten malignant cases lately with sudden coma as first sign of illness. The mortality from malaria was stated to be about 20 per cent., "probably more." Eight-tenths of all cases of illness in the town were malaria. The last year for which statistics are available is 1914, when 16,180 cases of malaria were registered out of a population of 140,800. The largest monthly number of cases were registered in August and December. Men were most affected between 20 and 40, women between 15 and 30.

Suggested Measures for Sanitary Organisation.

The public health organisation for dealing with these conditions was not adequate. The town was divided into six districts, and for each of these areas a sanitary medical officer was appointed. But each "sanitary medical officer" held three, four, or more other appointments of a clinical kind and had, in consequence, very little time to devote to his duties. Also, each sanitary officer had only two men to assist him in each district, who were paid and rationed on a low scale, and no transport of any kind.

As I was asked for suggestions I made those obvious ones connected with drainage, treatment by oil and removal of rubbish, familiar to all with any experience of antimalarial work, and, in addition, suggested that the "sanitary medical officers" should be relieved of all

FIG. 1.—Map issued by the Soviet Commissariat of Health for educational purposes to show the principal routes of the spread of cholera from India.

other work but paid the salary for all appointments relinquished; and, further, that the sanitary personnel should be largely increased (to 24 for each district), supplied with transport, and paid and rationed on the Red Army scale, and selected from those having knowledge of sanitary matters, or, failing these, from people of education who would appreciate the importance of sanitary work. I also suggested that a small fee should be paid for notification of infectious disease by doctors, sanitary service men, or representatives of the trade-unions. Other detailed suggestions were made regarding general cleanliness and for dealing with and preventing cholera and plague. Mr. Sverdlov travels with an advisory medical officer on his staff of experts, and this officer (a woman, Dr. Dmitrieff) entirely concurred in my suggestions.

The Town as a Danger Centre.

The existence of Astrakhan as a centre of malarial infection is serious enough (I was glad to get all my own party away without any of them falling ill), but when it is realised that it is one of the chief places from which cholera and plague spread it is difficult to exaggerate its importance. Last year there were 600 cases of cholera in Astrakhan and a very limited traffic on the Caspian Sea and on the Volga. This year a great many cases are expected, and there is much traffic on the Caspian Sea and the Volga, while the condition of the waterworks can only be described as admirably arranged to spread an epidemic. From

Astrakhan the cholera will spread up the Volga and through Russia. The map (Fig. 1), issued by the Commissariat of Health for educational purposes, shows the probable routes of infection. How near it will come to Western Europe remains to be seen. I was told that cholera comes to Astrakhan from up the Volga, that it increases in virulence in Astrakhan, and then spreads up the river again. The kind of poster propaganda undertaken by the Russian Government is shown in the illustration (Fig. 2), but is reinforced in the original by a picture below the one reproduced showing a cholera patient receiving intravenous injections in hospital. There was no plague in Astrakhan or on the Steppe to the East at the time of my visit, but

DESCRIPTION OF PROPAGANDA POSTER.

The illustration given on the opposite page is part of a Soviet propaganda poster showing the path of infection in cholera by means of water and flies. In the original poster a panel below portrayed a cholera patient in extremis being treated by saline injection. A microscope and a microscopic field of cholera germs were also pictured. The Russian text printed on the poster is as follows:—

PROLETARIAT OF ALL COUNTRIES, UNITE!

Cholera is a contagious disease, attacking principally those who live in dirty, poor, and overcrowded districts.

The great scientist, Robert Koch, discovered that cholera is caused by certain microbes.

These microbes are the smallest living atoms, which can be seen only by the help of a microscope, and are called cholera germs.

The symptoms of a light attack of cholera are diarrhoea, and sometimes sickness.

The symptoms of a severe attack are diarrhoea, sickness, great loss of flesh, coldness and blueness of the whole body, stopping of the urine, and cramp.

On the second or third day, and sometimes in a few hours, it can end in death.

Those who recover carry the germs for some time and may infect others.

Flies often carry the germs of cholera from the motions of the sick to food and objects of domestic use.

Especially dangerous is the infection by cholera germs of the water-supply, causing widespread epidemics among the population using the springs.

The cholera germs cause infection only when the microbe enters the intestines either by way of the mouth in food or drink, or by dirty hands. Milk, vegetables, fruit and other products bought at the markets or from hawkers may be infected by cholera.

Together with the motions containing the cholera germs, the contagion infects the soil, clothes, domestic utensils, food and drinking water and through them is carried to other people.

Uncovered water-supplies cannot be effectively protected from dirt, consequently this water can be used only after having been filtered or boiled.

In cases of cholera infection, hurry at once to the hospital, only there can you receive the necessary help. The placing of the sick in hospital removes the danger of spreading the disease among relatives and neighbours.

if it comes there is nothing to prevent its spread. Amoebic dysentery is also very serious in the town and neighbourhood, and there had been 100 cases of operation for hepatic abscess during the last 12 months.

Typhus and relapsing fever had devastated Astrakhan last winter as every other place in Russia, and I was told a story of the marching out of a Cossack army toward the Caucasus and the finding of some thousands of unburied bodies on the ground a day or two's march from the town, where an epidemic had stricken the army down. No really reliable statistics over a long period were available since 1914, but I give here the number of cases of actual illness of certain kinds on June 7th as stated to me by the chief medical officer, and which do not include malaria or dysentery.

Cases of Infectious and other Serious Illness at Astrakhan in Hospital on June 7th, 1920.

Scurvy	642 cases.	Typhoid fever ...	14 cases.
Relapsing fever ...	306 "	Small-pox	6 "
Typhus fever	196 "	Indefinite fevers ...	29 "

There were stated to be "casual cases" of diphtheria and "quite a number of deaths" from measles. Vaccination (in contradiction to what I was told at the

FIG. 2.—A SOVIET PROPAGANDA POSTER. (*Description on opposite page.*)

FIG 3.—Part of a Soviet propaganda poster showing effects of small-pox with recommendation to seek vaccination. On the original poster is a group of children and adults being vaccinated. The Russian text runs substantially thus: "Many die from small-pox, many become blind, and those who recover remain pock-marked. To protect yourselves from small-pox is easy; you must be vaccinated several times during your life. The fulfilment of the law of vaccination is the duty of every citizen of the Republic. Vaccinate yourselves against small-pox, and repeat the vaccination not less than every five years."

Commissariat of Health in Moscow) was said not to be compulsory; it was also said that there was a lack of vaccine and that the practice of vaccination had slackened during the revolution. Propaganda in favour of vaccination is also being done by poster, the upper part of one, showing effects of small-pox, being reproduced here (Fig. 3), while underneath (not reproduced) is a picture of a doctor and nurse vaccinating children brought by their parents.

Hospital accommodation was both insufficient and bad. Immediately outside the window of one of the main wards of the hospital was the edge of an oozing mud of faeces from the hospital cesspool, which covered a large area of the garden. I was told nothing could be done for the familiar reasons. It was another case of "Nitchewo." The ward was full of flies, which, of course, swarm everywhere. The general arrangements of the hospital were not good, it was dirty and untidy, and there was an almost complete absence of drugs and dressings, including chloroform and ether.

A certain amount of soap is made locally from seal-fat and fish-fat. It is a repulsive compound with a strong and nasty smell. Some of it was on sale in the market, dark brown in colour and looking like a greasy half-brick.

A Sanitary Commission Needed.

The state of affairs revealed in Astrakhan is dangerous, not only to that town and the Volga basin, but to the whole of Russia, and through Russia to Western Europe. Astrakhan is the chief port of the Caspian Sea and is connected by important trade routes with Persia and the Near East through Enzeli and with Turkestan and the further East through Krasnovodsk. Through Astrakhan flows the great river traffic up the Volga with direct river connexions reaching to Petrograd and Moscow. Both by railway and sea Astrakhan is also connected with Baku and Petrovsk. It is thus of the greatest importance that Astrakhan should be put into a sanitary condition at the earliest possible moment. At present the town is a fortress or headquarters of disease from which it may sally at any moment to invade the rest of the world. I have reason to believe that the Soviet

Government would consider the question of receiving a foreign sanitary commission to put matters into good order, and among the first tasks of such a commission would be: (1) extensive anti-malarial measures; (2) provision of special hospital accommodation for malaria and other infections; (3) general de-lousing and disinfection campaign; (4) repair and improvement of waterworks; (5) general cleanliness campaign; (6) provision of system of medical inspection of steamers arriving and departing and of travellers arriving by boat, by train, or otherwise.

Similar Conditions Rule Elsewhere.

I have dealt with Astrakhan in some detail because it is the town I have most detailed information about in Russia and because of its own individual importance, also because I believe it to be typical of the conditions now existing in many provincial towns in Russia. Streets are very commonly extremely dirty—the streets of Samara were as dirty as those of Astrakhan, although those of Saratoff were much cleaner; general housing conditions in the villages are described as very bad by the Commissar of Public Health. Vermin infection is excessively common. Statistics supplied me at Saratoff show that parasitic infections increased by 1500 per cent. between the middle of 1918 and the middle of 1919. The morale of the medical personnel has suffered seriously in the long war and revolution, and some have given up hope of change for the better. Also nearly all doctors are overworked. In many places there are no doctors at all. In the whole Astrakhan province outside the town I was told that there was only one doctor. And there is an almost complete lack of medicines, dressings, disinfectants, and soap. Despite the great and heroic efforts of the Commissariat of Health the organisation of civilisation is literally, as at Astrakhan, crumbling to pieces. It seems to me a condition in which the medical profession of this country might well offer the services of a non-political mission of help and health to our Russian colleagues, who are tried so much beyond their strength. The financial and political arrangements could perhaps be made directly by the Governments concerned.

(To be concluded.)

CLINICAL TEACHING AT LONDON SCHOOLS OF MEDICINE: THE PROFESSORIAL UNITS.

As stated in the leading article of our Students' Guide, published on August 28th, a representative of THE LANCET recently visited the five medical schools which have adopted the clinical unit system to ascertain the structure and proposed functions of the professorial units. In all cases the innovation is so recent that the arrangements are to be regarded as tentative and experimental. Nevertheless, it is clear that there are distinct divergencies of practice which are of importance only in so far as they depend on differences of principle and not on local conditions. It will be instructive to watch the future development of the clinical units in the five schools, as it is impossible to determine at present whether the differences are fundamental and likely to increase or whether they will tend to disappear. We have not attempted to indicate the arrangements for research, which are in most cases still incomplete, but it may be reiterated that the whole conception of the unit system depends on the choice of a clinical teacher from among those who are actively engaged in medical investigation and research.

St. Bartholomew's Hospital Medical School.

The unit staff of St. Bartholomew's Hospital Medical School is as follows:—

Medical.—Director; Vacant (full time). Assistant Director: Dr. F. R. Fraser (half time). Assistants: (1) Dr. A. E. Gow; (2) Dr. G. Graham (three-quarter time). Resident House Physician.

Surgical.—Director: Mr. G. E. Gask (full time). Assistant Director: Mr. T. P. Dunhill (half time). Assistants: (1) Mr. R. Ogier Ward; (2) Mr. G. L. Keynes (three-quarter time). Resident House Surgeon.

The professorial clinical unit, as it is called at St. Bartholomew's Hospital, consists of surgical and medical firms, differing from the non-professorial firms mainly as follows:—

1. Since the directors are continuously in hospital the routine superintendence of patients is done in the mornings or at any odd times, so that the official "round" can be devoted to the demonstration of cases interesting to the students.

2. The units have their own laboratories, all on the same floor, where full pathological investigations, including morbid histology, Wassermann and Widal tests, chemical pathology and bacteriology are performed by the unit staff, who also do their own post mortems. In cases of difficulty reference can be made to the appropriate department of the pathological institute.

Clinical work.—As to the order in which clinical appointments are held, great latitude is allowed to students at St. Bart's. A typical student, after passing intermediate, does six months' consecutive in-patient dressing. He may dress for any one of five surgical firms, of which the unit forms one, and this post includes dressing in casualty, though not in the out-patient department. At St. Bart's the casualty department is under the supervision of members of the honorary staff, and deals with a large number of cases which in many other hospitals would be treated as surgical out-patients. Certain cases, perhaps six or eight, of special interest for teaching purposes are selected and these only are referred to the out-patient department, where old in-patients, followed up on a card index system, are also seen. The director and assistant director each spend one morning in casualty and teaching in the out-patient department. There they are attended by senior out-patient dressers and not by the dressers to the unit firm. The beds allocated to the unit are shared by the directors. This arrangement is peculiar to the professorial unit since the members of the senior staff at St. Bart's do not see out-patients. In order to ensure a complete investigation and discussion on all cases the bacteriologist to the hospital accompanies the director on his rounds from time to time, while the lecturer on morbid histology pays regular visits to the unit laboratories and demonstrates on the microscopical sections of the cases. After six months in the surgical wards a student acts as clerk to the in-patients to a medical firm other than the professorial unit for three months, and then proceeds to the out-patient departments, to courses on fevers, pathology, and so forth. He then returns to the wards for a second three

months' clerking, and it is these senior students who, as far as vacancies allow, become clerks to the medical unit. The medical clerk attends out- as well as in-patients with the unit staff. Private rounds are done in the morning while the student works up his cases; the afternoons are spent in formal teaching in the wards. In the past session Sir Archibald Garrod, the late director, devoted one afternoon to post-graduate teaching, from which the undergraduates were, however, not excluded.

Pathology.—Though, as has been emphasised, the unit undertakes its own pathology, the dressers and clerks are not expected to perform the actual investigations except the minor ones. The senior students learn post-mortem and other pathological technique in the pathological institute when attached as pathological clerks to members of the visiting staff.

Remarks.—In the future it is hoped that the unit, besides working as a firm, will organise combined demonstrations in medicine, surgery, and pathology on individual cases, to be attended by all students during their first period of clinical work. Detailed technique, such as splint application or the use of instruments of diagnosis, will probably not be taught in these demonstrations, where an attempt will be made to focus the attention of the student on the fundamental unity of all processes of disease, and on the close connexion between medicine, surgery, and pathology.

London Hospital Medical School.

The unit staff of London Hospital Medical School is as follows:—

Medical.—Director: Dr. C. H. Miller. Assistant Director: Dr. A. W. M. Ellis. Assistants: (1) Dr. G. Riddock; (2) Dr. Maitland-Jones. Resident House Physician. Assistant House Physician.

Surgical.—Director: Mr. H. S. Souttar. Assistant Director: Mr. E. C. Lindsay. Assistants: (1) Mr. W. S. Perrin; (2) Mr. G. E. Neligan. Resident House Surgeon.

The teaching activities of the London Hospital clinical units are centred in:—

1. A concentrated course of clinical medicine and surgery, one month each, through which every junior student must pass.

2. The organisation of special series of lectures, open to senior students and post-graduates, by experts, not necessarily members of the units, on their special subjects.

Clinical work.—The London Hospital student, having passed intermediate, spends the next three months as a pathological clerk, learning practical morbid anatomy and clinical pathology before entering the wards. Then the units take him over. He does a concentrated course of one month with each unit, comprising, on the surgical side, the elements of case-taking and of theatre work and dressing. He learns the technique of clinical examination; demonstrations of typical cases in the wards are given, also demonstrations in splint application and plaster work, and the students attend at operations. During this month the student has no duties outside those of the unit, and his time is fully occupied in getting a sound foundation before entering the wards as a dresser. On the medical side a month is taken up with learning the elementary principles of physiology as applied to medicine and the methods of clinical examination and of treatment. Demonstrations are held in the wards, out-patient departments, and children's departments. Besides these courses, which are taken by all students, a certain number—as many as possible of those who apply—do three months' dressing and clerking with the unit as a firm. This appointment differs from an ordinary post as clerk or dresser only in so far as the chief is on the spot all day to supervise, direct, and encourage the student. When possible the student does the second of his two three-months' post in the unit firm in medicine and in surgery. The units undertake neither systematic lectures nor revision courses at present. The former are given by the lecturers in medicine and surgery, and the tutorial classes by the appropriate tutor. The units at present confine themselves to the teaching of junior students, to organising series of special advertised lectures held for fourth and fifth year students and open to post-graduates, and to clinical teaching in the wards and out-patient department.

Pathology.—The students on the unit firm perform blood counts and investigations of sputums, urines, and so forth, but for their own edification only; all investigations are done also in the pathological department of the hospital. Ward laboratories are to be built in the future, where students may be required to do more work under supervision.

Remarks.—The system of note-taking in triplicate devised by Mr. A. J. Walton has been adopted by the units. The notes of the director and his assistant are kept separately, and belong to the unit. The notes of the house physician are filed with the hospital records, while the students' corrected notes alone are on the bed boards. These may be removed and kept by the student for future references.

St. Mary's Hospital Medical School.

The unit staff of St. Mary's Hospital Medical School is as follows:—

Medical.—Director: Dr. Wilfred Harris (half time at present). Assistant Director: Dr. C. M. Wilson (10-4, five days a week). Resident House Physician.

Surgical.—Director: Mr. W. H. Clayton-Greene (half time at present). Assistant Director: Mr. C. A. Pannett (10-4, five days a week). Resident House Surgeon.

At this school the chief changes coincident with the establishment of the clinical units are:—

1. The rearrangement of the time-table in order to leave free the hour 12-1 for all hospital students to attend demonstrations given on alternate days by the medical and surgical units. Cases are allocated to senior students, who are encouraged to consult the literature and to demonstrate and discuss not only the individual case but the ætiology and the pathology of the disease.

2. In order to enable students to have a thorough experience in diseases of children and in chronic cases arrangements have been made for amalgamation for teaching purposes with the Paddington Green Children's Hospital, the Maida Vale Hospital for Nervous Diseases, and the Paddington Infirmary. The teaching at the children's hospital is to come into operation next session; last session demonstrations were given from time to time at Maida Vale, and one afternoon in each week was allocated by each unit to a round at the infirmary with senior students. On one afternoon round, at which a representative of THE LANCET happened to be present, the cases demonstrated included senile gangrene of the toes, Pott's disease with spastic paraplegia, cellulitis following varicose ulcer, and advanced inoperable carcinoma of the intestine—none of these being cases ordinarily met with by students.

Clinical work.—The student at St. Mary's passes from his intermediate studies to the casualty department for two months, during which time he also passes through courses of elementary surgery and medicine and elementary clinical pathology. He then does three months' surgical in-patient dressing, followed by three months' in-patient medical clerking, in each case with the unit or one of the two other firms. After three months in the out-patient department he returns to the wards. The second three months in-patient clerking and dressing are usually done in the second hospital year.

At St. Mary's no definite courses of lectures are arranged by the unit, and neither the systematic lectures nor the junior clinical courses and demonstrations are given under its auspices. The units attempt to use the enormous quantity of material at the disposal of the teaching staff since the amalgamations and to train all the students to extract the utmost scientific information from their clinical work. The daily demonstrations are attended by all the students, and the ward and theatre demonstrations by the students on the post and by senior students. A feature of the ward teaching is the limitation of the numbers attending demonstrations, which entails their frequent repetition.

Pathology.—The pathology of the unit is done in the appropriate departments of the pathological institute, where senior students work under the supervision of the staff of the departments, who are responsible for its accuracy. On one afternoon in every week naked-eye specimens and microscopic sections are sent to the unit laboratory, where they are demonstrated by the surgical director with the clinical notes. The pathological technique is learnt by the student in due course when he does his pathological clerkship, and it is considered that no advantage would be gained by the medical clerk and surgical dresser if he were expected to do more than routine pathological investigations as well as his other duties.

St. Thomas's Hospital Medical School.

The unit staff of St. Thomas's Hospital Medical School is as follows:—

Medical.—Not yet formed.

Surgical.—Director: Sir Cuthbert Wallace (part time). Deputy Director: Mr. B. C. Maybury (part time). First Assistant: Mr. W. W. Wagstaffe (whole time). Pathological Assistant: Dr. S. C. Dyke (whole time). Resident House Surgeon.

The work of teaching is divided between the surgical staff and that of the unit; there has been no attempt on the part of the unit to take over or direct all the teaching. Owing to the composite nature of the student's education and the growth of special departments it is considered that the correlation of teaching must be the function of the dean and the body that governs the school and not of the unit.

The lectures that are now given in the medical school are modelled on the system which was instituted just before the end of the war. Instead of having lectures on medical medicine and surgery, a subject is taken and lectures on it are given by the members of the staff and of the unit who are best acquainted with the subject, and by the other departments, such as those of anatomy, physiology, radiology, &c., when these can help.

It is felt at St. Thomas's that it is especially necessary to avoid the unit's becoming an isolated realm within the school.

Clinical work.—The student at St. Thomas's after he has passed intermediate, and before he takes up his work in the hospital proper, passes through a course in elementary medicine, surgery, clinical pathology, bacteriology, and pharmacology which is intended to fit the student to benefit by the teaching in the wards. The teaching is shared by the departments concerned and the unit. It is an open point whether all or only a certain number should work under the unit as a firm. At present it is felt that a short period in the unit is of little use, and dressers are taken on for six months.

The actual teaching undertaken by the unit at present is as follows: (1) A teaching round for senior students. (2) Two rounds for junior students, one of which takes the form, frequently, of a clinical lecture demonstration. (3) An out-patient afternoon, in which out-patients and old ward-cases are seen. (4) The deputy director and the first assistant take one morning each in the sorting-room, where senior students are admitted to watch the practice of the hospital. (5) The deputy director takes a class once a week in surgical anatomy. In this class the dissected specimen and the live model are used side by side. This class keeps the unit in touch with the anatomical department. (6) The pathological assistant gives classes in physiology and pathology, and it is hoped that he may also be a link between the unit and the physiological department.

Pathology.—The pathological investigations which are required for each case the student conducts himself under the direction of the pathological assistant. The latter will have the benefit of the advice of the professor of pathology, thereby forming a link between the unit and the pathological department proper.

The unit laboratory accommodation is spacious, and consists of (1) a small laboratory for the pathological assistant; (2) a large laboratory where each student will have his own place; (3) a small departmental library or meeting-room; (4) an office.

University College Hospital Medical School.

The unit staff of University College Hospital Medical School is composed entirely of full-time officers as follows:—

Medical.—Director: Dr. T. R. Elliott. Deputy Director: Dr. J. W. McNee. Assistant in Neurology: Dr. F. M. R. Walshe. Resident House Physician.

Surgical.—Director: Mr. C. C. Choyce. Assistants: (1) Mr. E. K. Martin; (2) Mr. F. J. F. Barrington; (3) Pathologico-surgical Registrar, not yet appointed.

The important alterations which accompanied the establishment of clinical units at University College Hospital are as follows:—

1. The units assume entire responsibility for the whole of the systematic teaching, respectively, in medicine and surgery. This does not imply that the teaching is now confined to the personnel of the units, but that they have undertaken to organise it, and the lectures given by other members of the staff on subjects in which they are specially eminent or interested are given by invitation of the directors of the unit concerned. The tutorial and revision classes are held by members of the unit; no attempt is made to give revision classes for post-graduates.

2. All physicians and surgeons on the honorary staff now have an equal number of beds and all take out-patients. This arrangement is said to have the treble advantage that the senior and most experienced physicians and surgeons teach in out-patients' department, that students in any firm are enabled to watch a given case from the day of its appearance in the hospital until its discharge from the wards and after, and that the younger members of the staff are not hampered for many years by lack of beds.

3. The gift of £800,000 made this year to the medical school by the Rockefeller Board will enable a Unit in Obstetrics and Gynaecology to be established, also on a full-time basis, as soon as the necessary new buildings are completed. The school will then be equipped with three complete units.

Clinical work.—After passing his intermediate the typical student at the University College Hospital proceeds directly to the wards, where he spends six months as clinical clerk or dresser, four of which are on another firm and two on the unit firm, and six months as surgical

dresser, two of which are similarly on the unit firm. It is fortuitous whether students do medicine or surgery first, but in the opinion of the directors it is more advantageous to do medicine first and also to be attached to the unit firm for the last two months in either subject. In the future it is hoped by the directors that two months' work as clerk or dresser will be postponed to the second clinical year, so that the practical study of general medicine and surgery will be continued up to the end of the student's hospital career.

All students spend two months attached to each unit firm. On the medical side the unit clerks take cases among the tubercle patients under Dr. S. J. Martin, Dr. H. Batty Shaw, and Dr. F. J. Poynton; children and infants under Dr. McNee; heart cases under Dr. T. Lewis, and nerve cases under Dr. Walshe; and their time-table is arranged to include rounds with these members of the staff.

Pathology.—The pathology of the cases under the care of units is at present done in the pathological department, where the senior students hold clerkships and learn technique. The surgical unit proposes shortly to add to its staff a pathologico-surgical registrar, who will work in laboratories to be erected near the wards and will be responsible for the pathology. The sections will be cut and stained by students on the unit firm under his supervision; the pathological department of the hospital will thus not receive the pathological material from the unit firm as a routine, but will act as consultants when required.

On the medical side the unit clerks at present do the sputum and urines, but when laboratories are developed in direct connexion with the wards more pathological work will be done by the clerks and medical staff of the unit. It is considered that the students doing the clinical work must collect more of the pathological evidence themselves in order that they may learn to appreciate its value in diagnosis.

TUBERCULOSIS IN WALES:

THE WORK OF THE WELSH NATIONAL MEMORIAL.

TEN years ago this month the King Edward VII. Welsh National Memorial (Tuberculosis) Association was inaugurated. When the tuberculosis provisions of the National Health Insurance Act, 1911, came into force this Memorial Association, a voluntary institution owing its existence largely to the financial generosity of its president, Major David Davies, received support from various Welsh health authorities, who delegated to it their responsibilities with respect to the treatment of tuberculosis. Steadily through the last decade the Association has been consolidating its position, skilfully guided through some local opposition and many pitfalls by its general director, Mr. D. W. Evans.

The past 12 months has been especially momentous in its history. In the first place its position as a Welsh national institution was fully recognised when their Majesties, accompanied by Princess Mary, opened the North Wales Sanatorium for women and children at Llangwyfan, overlooking the far-famed Vale of Clwyd, and the South Wales Sanatorium for men and boys, placed in scarcely less beautiful surroundings at Talgarth; then it is able to record that the last outstanding health authority in the Principality, Pembrokeshire, has thrown in its lot with the Association, moved thereto by discovering that the expenses involved in a separate tuberculosis scheme would mean a 5d. rate as contrasted with the 1d. rate asked by the Association; next it can point out that a stern financial battle with the Treasury authorities to obtain full recognition has resulted in its favour; and, finally, it is enabled, owing to private generosity, to announce the foundation of a chair of tuberculosis in the Welsh National School of Medicine, the occupant of which is to be principal medical officer of the Association, so holding a unique position. These four facts are no mean achievements to record as the result of post-war activities.

The work of the Association is carried on by pooling the resources of the Principality; this enables the most up-to-date treatment to be established in economic units, surgical cases being drafted to specialised hospitals, medical cases to others, and sanatorium cases to yet other specialised institutions. Every advantage to the patients and to economic management is in this way

obtained. The Association has at its disposal, distributed over some 14 institutions, between 1100 and 1200 beds, a total which is being steadily increased. The medical staff numbers over 20 and is also being rapidly increased. These increases are needed to cope with the flow of work, as may be seen from perusal of the annual report for the year ending March 31st, 1920, which has just been issued with commendable promptitude.¹ The following summary table is of interest in this connexion:—

Patients.	1913-14	1914-15	1915-16	1916-17	1917-18	1918-19
Examined	8,763	8,868	9,155	10,739	11,780	12,260
Received sanatorium treatment	888	1,214	1,290	1,360	1,258	1,251
Received hospital treatment	1,185	1,789	2,178	2,504	2,551	2,380
Received institute treatment	3,722	5,203	4,720	4,690	5,143	4,867
Recommended for domiciliary treatment	1,200	1,634	1,944	2,924	3,317	3,548

The result of sanatorium treatment is summarised in the next table, which wisely is not brought forward further than 1918, since more recent figures in Columns 4, 5, and 6 would obviously be fallacious for comparison with previous years. Indeed, in relation to this table we should like to be informed when the figures for previous years cease to be revised. Some period, say five years, should be fixed, since, for instance, everyone included in Column 2 must with effluxion of time finally appear in Column 6.

Return of Patients who were Discharged from Sanatoriums from the Year 1912 to 1918.

Year.	Number discharged.	Well and at work March 31st, 1920.	Not well.	Left the district and cannot be traced.	Dead.
1912	42	13 (30.95%)	2 (4.77%)	9 (21.42%)	18 (42.86%)
1913	515	210 (40.79%)	35 (6.79%)	78 (15.14%)	192 (37.28%)
1914	790	341 (43.16%)	64 (8.10%)	104 (13.17%)	281 (35.57%)
1915	877	388 (44.24%)	77 (8.78%)	138 (15.73%)	274 (31.25%)
1916	894	440 (49.22%)	74 (8.27%)	115 (12.87%)	265 (29.64%)
1917	862	478 (55.44%)	93 (10.79%)	91 (10.56%)	200 (23.21%)
1918	879	505 (57.45%)	123 (14.0%)	79 (9.0%)	172 (19.55%)

One activity calls for special reference. The renewal of the education campaign under the direction of Dr. R. Owen Morris, which was developing on excellent lines when interfered with by the war. This campaign is built on the sound foundation that treatment will never eradicate tuberculosis, but that "the community must learn the principles and practice of hygienic living and the methods of prevention." This campaign should be more widely extended; 357 lectures in schools and 23 public lectures are insufficient for the Principality.

We note that a colony for training discharged Service men suffering from tuberculosis is being embarked upon in connexion with the Talgarth Sanatorium. Valuable information as to the efficacy of after-care through this form of industrial convalescence should in this way be obtained, which may be expected to result in the Association extending it from ex-Service men to civilians, victims of peace-time conditions. We feel some confidence that ere long no sanatorium will be considered complete without special workshops suited to the special needs of those local industries from which the patients are drawn.

The report further contains the welcome information that a scheme of research work only awaits the appointment of the principal medical officer to be undertaken. We have long felt the coping-stone the Association needed to its structure was closer coordination of medical work directed more particularly towards research, for which the facilities at the disposal of the Association are admirably suited. We look forward to information in the next annual report stating that action has commenced on these lines. From such action valuable results must ensue.

¹ Annual Report for the Year Ending March 31st, 1920, of the King Edward VII. Welsh National Memorial Association. W. Whittington Neath.

MEDICINE AND THE LAW

The Patient's Consent to Operation.

AT a recent inquest at Liverpool upon the body of a woman who had died in the infirmary after an anæsthetic had been administered for the purpose of an operation, relatives of the deceased complained to the coroner that they had not been informed that an operation was to take place, and that the patient had not consented to undergo it. Evidence was, however, given that the patient had been informed that an operation was necessary, and that she had raised no objection. The coroner's comment was to the effect that the written consent of the patient should be obtained if possible. Certainly the most desirable course, but one which it is not always possible to follow, is to obtain the signature of the patient to a written consent, or the patient's verbal consent in the presence of a witness or witnesses. Further, the reasons for the operation and its possible consequences should be explained to the patient, and any consent in writing should acknowledge that this has been done. In the case of children the consent should be that of a parent or guardian. The above, no doubt, is the ideal course, but in hospitals there must necessarily be occasions when an operation presents the only possible, albeit uncertain, means of saving life, and when the patient is not in a condition to give or to refuse consent. Also, when this occurs there may be no relative present, and it may not be possible to communicate with any relative without such delay as would endanger the patient's life. In such circumstances as these it is clearly the surgeon's duty to do his best in the patient's interest, and it may be pointed out that the presence of the latter in the hospital, if voluntary, is in the nature of a submission to the treatment to be decided upon by its staff. In the case of a man who is brought into a hospital as the result of an accident, and operated upon at once as the only possible means of saving his life, although his consent could not be obtained, it is hardly conceivable that relatives would complain or that a coroner or jury would listen to them if they did. The case of *Beatty v. Cullingworth*, in which a female patient sought for damages from a surgeon on the ground that, having obtained her consent to the removal of one of her ovaries, he eventually removed both, will be remembered. It points to the desirability of any authorisation of an operation being in general terms, so that the surgeon may be free to act as conditions may dictate.

The Conduct of Maternity Homes.

The keeper of a maternity home at Lewisham, the registration of which had been cancelled by the London County Council, appealed to the magistrate sitting at Bow-street. Mr. Graham Campbell, having reserved his decision for consideration, dismissed the appeal. The registration had been cancelled on account of the evidence as to the conduct and character of the appellant and as to the unsuitability of the premises and their equipment for their purpose. The magistrate upheld the decision of the Council on both points, and made an order that the appellant should contribute £50 towards the cost of the appeal. No one who has read the evidence as reported can doubt the correctness of this decision on the facts deposed to by the witnesses. With regard to the question of the appellant's moral character, it is, of course, desirable for all keepers of nursing homes to be persons of good character. In the case of establishments maintained for profit in order that women may be delivered of children in them, it is absolutely essential if the evil results connected with the traffic in "unwanted" babies are to be controlled.

The Duty of Anyone Finding a Dead Body.

In the case of the death of a girl named Irene Munro, apparently murdered near Eastbourne on the night of August 19th, comment upon any matters connected with the alleged crime would now be out of place. It is, however, permissible to deplore the

delay which apparently intervened between the finding of the dead body by a child accompanied by his mother and the informing of the police. Not only did this postpone investigation generally and quite unnecessarily, but it had as its result that the first medical examination of the corpse on the spot where it was found was made several hours later than it need have been, and at night instead of by daylight. To leave a dead body undisturbed is clearly right, in view of a possible crime, but to communicate the fact of its discovery immediately to the authorities is the simple duty of any citizen, and withal an act of common-sense.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Dangerous Economies of the Dublin Corporation.

THE economies resulting from the deadlock between the Dublin Corporation and the Government concerning the payment of Government grants towards local services are extending even further than was outlined in this column a week ago. Not only is the entire service as regards tuberculosis to cease, unless—an unlikely event—it can be carried on by public subscription, but the housing, the public health service, the provision of school meals for children, and other activities directly concerning the health of the people are all being seriously interfered with. Contributions to the Dublin Union and to the Richmond Asylum are to be decreased, so that these two necessary institutions will also suffer. Moreover, all employees of the corporation, of every rank, are to have 25 per cent. of their salaries or wages held back for nine months from Oct. 1st. It is likely that other public bodies will decide to exercise similar crippling economies, and the health of the country is bound to suffer.

The late Mr. Robert Campbell.

The Belfast Medical School and the whole profession in the North of Ireland have sustained a great loss by the death, on Sept. 6th, of Mr. Robert Campbell. Mr. Campbell had been for years one of the most sought-after consulting and operating surgeons in Ulster. In March of this year he had a cerebral hæmorrhage, from which he recovered sufficiently to resume practice, but three weeks ago an acute attack of Bright's disease, the chronic nephritis from which he had suffered since his boyhood, became acute and he died from uræmia in his fifty-fifth year. The son of a clergyman, Mr. Campbell was born at Templepatrick, County Antrim, and was educated at the Royal Academical Institution and later at Queen's College, Belfast. He obtained the Coulter exhibition (for clinical excellence) at the Royal Victoria Hospital in 1891, and graduated M.B. R.U.I. in 1892, and became F.R.C.S. Eng. in 1896, when he started practice in Belfast. In 1898 he was appointed surgeon to the Belfast Hospital for Sick Children, and in 1900 he became assistant surgeon to the Royal Victoria Hospital, Belfast. With these two institutions he remained connected until his death. During the war he was surgeon to the Ulster Volunteer Force Hospital. Mr. Campbell was a member of that body of able professional men in Belfast who owed much of their subsequent success to the thorough training in anatomy they received from one of the most inspiring teachers of his time—the late Dr. Redfern, professor of anatomy at Queen's College, Belfast; and they revolutionised surgery in the North of Ireland. His publications include "The Operative Treatment of Hernia in Infants and Young Children, Illustrated by 114 Consecutive Cases," published in THE LANCET of Jan. 9th, 1904, and articles on the operative treatment of perforated typhoid ulcer, thyroidectomy for exophthalmic goitre, and acute appendicitis, in the Transactions of the Ulster Medical Society, of which he was at one time President. Mr. Campbell had the complete confidence of those of his professional brethren who were best able to judge of his skill, while the public at large were impressed with what to them is, after all, the real test, the success of his operative work. Mr. Campbell was a strong personality, dogged, persevering, and

determined (despite his own ever-present ailment) to do the very best for his patients in any emergency. He possessed the rare power attributed to the Greeks of thinking before he acted and of acting too. With a rather reserved and silent manner, he was full of the keenest humour. His strenuous life, his splendid work, and his upright conduct will long be an example to be followed in the Belfast Medical School.

Officialdom and War Pensions.

The proposal made at the last meeting of the Tyrone War Pensions Committee to appoint two whole-time sub-secretaries for the different sub-committees met with much criticism. Dr. E. C. Thompson said new officials were unnecessary, and would only add to the already intolerable burdens of the county. If the Pensions Ministry would only diminish and revise their regulations, there would be little difficulty in carrying on all the work necessary for wounded soldiers. The general feeling was that the interests of the wounded men were being submerged in officialdom, and that the men wanted their pensions arranged at once and to be released from hospital. A resolution embodying these views having been proposed, it was seconded by Dr. Thompson, passed unanimously, and sent to the Ministry of Pensions.

Sept. 14th.

Public Health.

REPORTS OF SCHOOL MEDICAL OFFICERS.

CARLISLE.

Of the 7100 children in average attendance at the schools in Carlisle during 1919 more than half (3630) were medically inspected at the routine examinations, or as special cases, or at visits of reinspection during the year. Of the first-named group, numbering 2814, 35 per cent. were found to be suffering from some defect requiring immediate attention, and a further 28 per cent. were directed to be kept under observation.

Nutrition was considered defective in 9.23 per cent., but only in three children was any actual treatment required. Cleanliness on the whole is improving, as shown by a table of the conditions found during the last ten years; but at two surprise visits vermin were found in the heads of girls in 9.3 and 5.9 per cent. respectively, and nits in 26 and 27.9 per cent. of the 3000 odd children examined. This shows that a great deal has still to be done in the way of education of the parents as to their duties. No arrangements are made by the education committee for the cleansing of verminous children, and Mr. Joseph Beard, who presents this report as medical officer of health and school medical officer, doubts if much benefit would result therefrom. There were only 33 cases of scabies found at the routine examinations, the total number found being 146, a considerable improvement over the two years preceding. There were only 11 cases of ringworm among the code group children, but the total number of cases was 115, and 13,289 "school days" were lost (averaging 116 per child). X ray apparatus has been installed and no doubt there will be a considerable saving of school time during the present year. Thirty-one children were found to be suffering from organic heart disease, but in only 2 cases was treatment considered necessary; the remaining 29 children, together with 37 cases of functional heart disease, are noted as to be kept under observation. It may be permissible to doubt whether any child with definite organic disease of the heart can be properly considered *not* to require treatment—that is, not only careful management and supervision with regard to diet, exercise, and instruction, at home, in the school-room, and the playground, but also medical examination at frequent intervals to determine the cardiac condition. If merely recommended "to be kept under observation" such cases are apt to be overlooked. Sudden death from morbus cordis in school or in the playground is a catastrophe to be guarded against in every possible way.

With regard to visual defects, it is stated that 583 children were referred for examination by the oculist; out of 186 cases of refractive error, hypermetropia and hypermetropic astigmatism accounted for 138, while of myopia and myopic astigmatism there were only 32 cases. Except for measles (670 cases), which was prevalent from September to December, there was no epidemic outbreak of importance.

A very interesting account is given of the results of tuberculosis treatment during recent years in Carlisle. The disease became notifiable in 1911; since then 732 children under 14 have been notified, of whom 362 were males and 370 females; 530 suffered from pulmonary tuberculosis, and of these cases the disease has been arrested in 63 per cent., while in 10 per cent. it is still active; among the remainder 52 are known to have died, 3 have been killed on active service, and 72 cannot be traced. Of 113 children who received sanatorium treatment for the lung affection the disease has been arrested, or is quiescent, in 76; in 26 the disease has not been arrested, 7 have died, and 4 cannot be traced. Among 50 cases of glandular tuberculosis the disease has been arrested in 42. Of 732 children notified as suffering from all forms of tuberculosis in the period 1911-1918, in 60.8 per cent. the disease has been arrested, in 9.6 per cent. it is still active, 16.9 per cent. have died; the remainder (12.7 per cent.) cannot be traced. "The high percentage of cases arrested or cured is extremely gratifying, and is a distinct encouragement to take all steps possible to search out tuberculosis in its early stages and apply prompt treatment."

CARDIGANSHIRE.

In Cardiganshire previous to 1919 there had been no medical inspection of school children for more than two years. During 1919 it was resumed and 3006 children were systematically examined, besides 187 special cases. In only 653 cases were the parents present.

Not more than 29 children (of whom 27 were boys, according to the table on p. 12 of the report) were returned as "ill-nourished," but Dr. L. Meredith Davies, the school medical officer, states that "the general physique of the majority of the children is very poor." The two statements are difficult to reconcile. A child may be below normal as regards physical development and yet be in good health; but if the general physique is considered to be "very poor" it seems inconsistent to return "malnutrition" in only 29 cases out of 3000 children. In regard to provision of a mid-day meal there are difficulties. No doubt many of the children come some considerable distance to school. It appears that in eight schools some provision is made, but 78 schools "either do nothing or provide hot water or tea or cocoa." The condition of the schools as regards sanitary matters appears to be in many instances unsatisfactory; insufficient water-supply and washing arrangements, the continued existence of middens and privies, and inadequate methods of sewage disposal are mentioned. Dry cleaning and dusting of the school-rooms is still the common practice. As Dr. Davies says, "it is mostly by means of education that one can hope to improve the deplorable condition which exists." Some useful suggestions are made, which, it is to be hoped, may speedily be carried out; these include provision for drying children's clothes, as many of them "have several miles to walk in the morning before reaching school," and arrangements for children coming from a distance, by which "the meals should be served in an orderly fashion, with tablecloth and proper cutlery on the table. Teachers and monitors should be appointed to superintend the meals." (The educational value of such a meal might be considerable.) The provision of dual desks, and the importance of the proper direction and regulation of window lighting are also very rightly insisted on. Many other matters of educational and sanitary importance are dealt with in this interesting report, which, unfortunately, has many typographical errors; these, however, as well as many of the conditions calling for improvement in the schools referred to, may perhaps be attributed to difficulties of communication. The "sweet shire of Cardigan" yields to none in the Principality for historical interest and beauty of scenery, but its railways are few and roads none of the best. Improvement will come in time.

CHESTERFIELD.

At Chesterfield 1726 children were systematically examined in the code groups during 1919, as well as 316 special cases.

The nutrition was on the whole satisfactory, only 12 among these 1726 children being considered to be badly nourished. (Table, p. 9. In table on p. 14, referring to nutrition, and also apparently applying to the same groups of children, 25 are stated to be badly nourished.) The most numerous defects found were those of the teeth (7.65 per cent.), throat (4.86), and vision (4.40). Only 4 cases of pulmonary tuberculosis were definitely diagnosed (0.23 per cent.), but the disease was suspected in 22 other children (1.27 per cent.). No provision for open-air classes has yet been made in Chesterfield. Dr. R. Fraser urges the importance of this matter, and points out that it would be quite easy to arrange for classes to be held in the playgrounds, suggesting also that open-air instruction might be carried out in the parks of the town, as has been done at Nottingham. Free dinners were provided from November to February for 241 school children, 78.8 per cent. of these being the children of strikers. The cost of

the meals (meat and vegetable stew, followed by a milk pudding) averaged 5d. per child, and the results were evidently satisfactory. There was no infectious disease of importance in any school necessitating closure except a few cases (3) of scarlet fever at Hasland C.E. school, but measles (127 cases) and influenza (155) were somewhat prevalent.

URBAN VITAL STATISTICS.

(Week ended Sept. 11th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 9.9, 9.9, and 10.0 in the three preceding weeks, rose to 10.3 per 1000. In London, with a population of nearly 4½ million persons, the annual death-rate was 10.0, or 0.3 per 1000 above that recorded in the previous week, while among the remaining towns the rates ranged from 4.4 in Merthyr Tydfil, 5.1 in Reading, and 5.6 in Southend-on-Sea, to 18.3 in West Hartlepool, 18.7 in Dewsbury, and 18.8 in Warrington. The principal epidemic diseases caused 259 deaths, which corresponded to an annual rate of 0.8 per 1000, and comprised 171 from infantile diarrhoea, 38 from diphtheria, 20 from whooping-cough, 14 from measles, 12 from scarlet fever, and 4 from enteric fever. The deaths from infantile diarrhoea, which had increased from 87 to 171 in the five preceding weeks, were again 171, and included 43 in London, 10 in Liverpool, and 9 each in Birmingham and Hull. The mortality from the remaining diseases showed no marked excess in any of the large towns. There were 2633 cases of scarlet fever and 1484 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 2402 and 1404 respectively at the end of the previous week. The causes of 19 of the 3506 deaths in the 96 towns were uncertified, and included 2 each in Birmingham, Warrington, Manchester, Rotherham, and West Hartlepool.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 10.8, 11.1, and 9.8 in the three preceding weeks, rose to 11.2 per 1000. The 239 deaths in Glasgow corresponded to an annual rate of 11.2 per 1000, and included 11 from infantile diarrhoea, 3 each from whooping-cough and diphtheria, and 2 from small-pox. The 69 deaths in Edinburgh were equal to a rate of 10.5 per 1000, and included a fatal case each of infantile diarrhoea and diphtheria.

Irish Towns.—The 112 deaths in Dublin corresponded to an annual rate of 14.1, or 0.4 per 1000 above that recorded in the previous week, and included 17 from infantile diarrhoea. The 132 deaths in Belfast were equal to a rate of 16.7 per 1000, and included 7 from infantile diarrhoea and 2 from scarlet fever.

MANCHESTER FRENCH HOSPITAL.—A course of five post-graduate lectures is being held on Thursdays, in September, at 4.15 p.m. The two lectures still to be given are by Dr. A. C. Magian, on Tubal Abortion (Sept. 23rd) and Ovarian Pregnancy (Sept. 30th). Medical men will be cordially welcomed.

The Services.

THE RANK OF NAVAL MEDICAL OFFICERS.

It has been decided by the Admiralty that medical officers who entered the Service on or after August 4th, 1914, will not have to pass a qualifying examination for the rank of surgeon lieutenant-commander. These officers, however, when they have obtained between two and six years' seniority in that rank, and after a preliminary course of study, will have to qualify by examination for promotion to a higher grade. Surgeon lieutenant-commanders will be eligible for accelerated promotion according to the class of certificate obtained in the qualifying examination after having been recommended for advancement. Surgeon lieutenant-commanders who fail to pass at a second trial will be compulsorily retired with a gratuity which shall not exceed £100 for each complete year's full-pay service, nor be above a maximum of £1000. Officers who entered the Service before August 4th, 1914, may voluntarily take the course and sit for the examination.

Payment of provision allowance instead of hospital allowance will be made to all medical officers serving in naval hospitals and other establishments at home, with retrospective effect to July 1st, 1919, where the officers victual themselves, and no advantage is obtained from the purchase of provisions at Government rates. In the case of medical officers serving in naval hospitals and establishments abroad the provision allowance should be substituted for the hospital allowance, subject to the conditions stated.

THE COLONIAL MEDICAL SERVICE.

The conditions under which medical men may join the various colonial medical services were set out in the columns of our Students' Number on August 28th, and as we then indicated alterations tending towards improvement in the working of the services were to be expected in the near future.

The Committee appointed in November, 1919, to inquire into the Colonial Medical Services, which included the names of Sir William Leishman, Sir James K. Fowler, and Sir Humphry Rolleston, has now presented a report, the main recommendations of which are as follow: (1) A unified service. Hitherto a candidate has applied for appointment in a special colony; the Committee recommends that in future admission should be to "The Colonial Medical Service." (2) The appointment of a director-general, to advise on all matters relating to the personnel of the Service. (3) That candidates should be recently qualified medical men who have held some resident hospital appointment. (4) The selection of candidates by competitive examination, which might be general for all the public services. Candidates to be interviewed and approved before being examined. The examination would serve, in the Committee's opinion, to bring the existence of the Service before the bulk of the medical profession, to whom it is at present almost unknown.

The report deals with pay—a minimum of £600 per annum is recommended—pensions, leave, and promotion. The hope is expressed that the adoption of the measures suggested may remove the present causes of discontent and raise the Colonial Medical Service to a high place amongst the public medical services of the Empire.

In a letter addressed to the chairman of the Committee and printed as an appendix to the report, assurance is given of Lord Milner's interest in the recommendations, some of which have already been carried out in particular colonies.

DEATH OF SIR WILLIAM BABBIE, V.C.

Lieut.-Gen. Sir William Babbie died on Sept. 11th in Belgium, where he was spending a holiday. He was born on May 7th, 1859, the eldest son of John Babbie, J.P., of Dumbarton. Educated at Glasgow University, he became M.B. Glasg. and L.R.C.P., L.R.C.S. Edin. in 1880, entering the Army Medical Service in the following year, and reaching the rank of Major in 1893. During the international occupation of Crete in 1897-98 he served as senior medical officer, receiving for his services the C.M.G. Throughout the South African War he was on the staff of the Natal Army, being present at all the actions for the relief of Ladysmith and at the subsequent operations in Natal and Eastern Transvaal. It was at Colenso that he won the Victoria Cross for his courage in attending the wounded under fire and in attempting to save Lord Roberts's son. At this time he was promoted Lieutenant-Colonel and received the medal with five clasps. Along with initiative and great personal courage Babbie's abilities as organiser and administrator had already shown themselves, and after serving from 1901-06 as assistant and from 1907-10 as Deputy Director-General he became in 1914 Director of Medical Services in India, and later filled the same office in the Mediterranean.

Nominally responsible in part for the medical defects in the expedition to Mesopotamia, his work came under the survey of the Commission of Inquiry, which, however, made it clear that his tenure of a responsible post when war broke out had been very brief, while the atmosphere in which he worked was unfavourable to reform. The Army Council therefore justly decided to retain General Babbie's services as Director of Medical Services to the War Office, and in 1916 he was appointed K.C.M.G., being promoted K.C.B. in 1919. Since 1914 he had been honorary surgeon to the King.

AWARD OF THE VICTORIA CROSS.

The King has approved the award of the Victoria Cross to the late Temp. Capt. Henry John Andrews, M.B.E., of the Indian Medical Service—

"For most conspicuous bravery and devotion to duty on Oct. 22nd, 1919, when as senior medical officer in charge of Khajuri Post (Waziristan) he heard that a convoy had been attacked in the vicinity of the post and that men had been wounded. He at once took out an aid-post to the scene of action and, approaching under heavy fire, established an aid-post under conditions which afforded some protection to the wounded but not to himself.

"Subsequently he was compelled to move his aid-post to another position, and continued most devotedly to attend to the wounded.

"Finally, when a Ford van was available to remove the wounded, he showed the utmost disregard of danger in collecting the wounded under fire and in placing them in the van, and was eventually killed whilst himself stepping into the van on the completion of his task."

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Lieut. (Dental) F. W. Paul to be Surgeon Lieutenant-Commander (Dental).

ROYAL ARMY MEDICAL CORPS.

Lieut.-Colonel R. J. W. Mawhinny relinquishes the temporary rank of Colonel.

Lieut.-Col. H. S. Roch relinquishes the acting rank of Colonel.

Major T. T. H. Robinson relinquishes the acting rank of Lieutenant-Colonel.

Capt. and Bt. Major M. J. Williamson to be acting Lieutenant-Colonel.

Capt. F. C. Tibbs and Temp. Capt. D. Miller and W. B. Swete-Evans relinquish the acting rank of Major.

Capt. J. C. Preston, from Spec. Res., to be Captain.

Major W. Bruce, from N.Z. Med. Corps, to be Captain.

Capt. N. Cantlie is seconded for service with the Egyptian Army.

The undermentioned Captains are restored to the establishment: W. C. Hartgill, C. D. M. Buckley, T. J. L. Thompson.

Capt. H. L. C. Noel resigns his commission.

Temporary Captains relinquishing their commissions and retaining the rank of Captain: F. C. Plummer and C. G. Burton.

SPECIAL RESERVE OF OFFICERS.

Capt. W. W. Shorten relinquishes the acting rank of Major.

Officers relinquishing their commissions:—Capt. K. D. Murchison (granted the rank of Lieutenant-Colonel). Captains retaining rank of Captain: M. C. Cooper, T. H. Rhys, T. O'Mahoney, H. J. Blampied, S. H. de G. Pritchard, C. A. W. Ramsay, C. Tighe, G. F. Hurst, J. A. Pantton, J. W. W. Baillie, M. O. Simpson, R. S. Corbett, F. J. Charlton, E. O. Goldsmith, E. R. Batho, P. S. G. Cameron, D. C. Beaumont, H. G. V. Mence, D. V. Murphy, J. S. B. Forbes, J. McKay, R. S. Aspinall, C. Shearer, J. S. Graig, G. M. S. Smith, R. P. Smith, A. Piney, J. W. W. Newsome, D. J. MacKinnon, J. C. Pyper, C. L. Somerville, J. B. S. Lewis, J. McI. H. Smellie, J. S. Bow, J. Ashforth, L. C. Moore, J. A. Ross, M. J. Cahalane, C. Wood, J. J. Conybeare, W. M. L. Gabriel, W. V. Robinson, R. A. Olphert, A. D. Fraser.

TERRITORIAL FORCE.

Capt. O. Teichman to be Deputy Assistant Director of Medical Services, 2nd London Division.

Major A. C. Oldham and Capt. B. M. Footner are seconded under para. 112, T.F. Regulations.

Capt. E. Alderson to be Major.

Capt. A. M. Davie and A. M. Mackay resign their commissions and are granted the rank of Major.

Captains resigning their commission and retaining the rank of Captain: D. M. Johnston, C. W. Greene, F. C. Pridham, G. C. Soutter.

supernumerary for service with the Officers Training Corps, Belfast University Medical Unit Contingent, Sen. Div.: Capt. G. G. Lyttle relinquishes his commission.

ROYAL AIR FORCE.

Capt. (acting Lieut.-Col.) J. J. C. Hamilton is transferred to the unemployed list.

INDIAN MEDICAL SERVICE.

Major M. Ba-Ketto to be acting Lieutenant-Colonel while commanding a Combined Field Ambulance.

Majors W. S. McGillivray, G. Holroyd, W. E. Brierly, and Capt. G. L. Duncan to be acting Lieutenant-Colonels while commanding an Indian General Hospital.

Capt. J. P. Huban to be acting Lieutenant-Colonel while commanding an Indian Field Ambulance.

Capt. P. B. Bharucha and Temp. Capt. B. B. Shah, W. M. Will, and E. C. Brooks to be acting Majors while Registrars of an Indian General Hospital.

The King has approved the retirement of the following officers: Col. P. C. H. Strickland, and Lieut.-Col. J. Mulvany.

The King has approved of the resignation of Capt. P. S. Connellani. Temporary Captains relinquishing their commissions: Narayan Lakshman Sheory and Vinayak Mahadeo Phatak (granted the rank of Captain).

Correspondence.

"Audi alteram partem."

NYSTAGMUS AND ILLUMINATION.

To the Editor of THE LANCET.

SIR,—Your annotation on this subject is timely and interesting, as at the present moment the construction of a better miner's lamp is under consideration by a special committee in London. Dr. T. L. Llewellyn is an indefatigable worker, and the point of interest to me in his Brussels paper—a copy of which he kindly sent me—is the much greater effect on illumination that is brought about by whitewashing the walls than by increasing the candle-power of the lamps. He informs me that the effect of stonedusting is not as good as whitewash, but very striking, and that 200 yards of roadway can be stonedusted in less than five minutes by the compressed air method. I hope that he will be able to persuade colliery owners to go a step further than the roads and carry it to the coal face where it is most needed.

As long as ten years ago I advocated introducing colour in coal mines,¹ and expressed the view that the cause of nystagmus was the absence of colour in them, but up to the present I have not heard of anybody agreeing with this theory. The thing that impressed me more than anything else on my first visit to a coal mine was the blackness and gloom of it. It seems almost incredible that miners should be content to work in such surroundings, and that owners do not realise how very different the mines could be made, and what an effect it would have on the workers if the surroundings were more cheerful. Sir Josiah Court, and Dr. Llewellyn up to quite recently, seem to have thought that the way to increase illumination was simply to have lamps with a greater candle-power, and declined to admit that absence of colour had anything to do with nystagmus. And yet the latter recognises that only from 3–10 per cent. of light is reflected, all the rest being lost by absorption by the black coal. To throw a great light on a black surface is a truly wasteful method of illumination. Now that roadways have been whitewashed it will be interesting to hear how much nystagmus occurs among men working in them. As far as I know there is none.

In a paper on Colour and Light in Relation to Miners' Nystagmus which I read at the Oxford Ophthalmological Congress in 1912² and again at the recent discussion by the Illuminating Engineering Society,³ emphasis was thrown on the importance of colour in mines, not only of the colour of the surface, but also of the colour of the light thrown on that surface. Lately things seem to be moving, and colour is being put into mines—but not enough yet—and also into miners' lamps by at least one manufacturer, who makes a lamp with a yellow globe. The light from this, although not perfect, is far preferable to the bluish light from a metallic filament lamp. On the whole, I fancy that Dr. Llewellyn and others may now be inclined to attach more importance to colour than formerly. Probably the vitiated air in mines is another factor that should not be ignored.—I am, Sir, yours faithfully,

Ebbw Vale, Sept. 12th, 1920. H. S. ELWORTHY, F.R.C.S.

WHEN IS AN ADVERTISEMENT NOT AN ADVERTISEMENT?

To the Editor of THE LANCET.

SIR,—In the leading article entitled "Your Telephone Number" in your issue of August 21st you raise the above question, and the answer is not easy. One might suggest various other questions of advertisement. Is publishing one's name in "Who's Who" an advertisement? I have been told that it is one of the best. Is writing a book on some specialty and advertising it in

¹ Brit. Med. Jour., Nov. 19th, 1910.

² Ophthalmoscope, December, 1912.

³ Illuminating Engineer, March, 1920.

the medical papers, year in and year out, an advertisement? The sale of the book cannot pay for it. And, lastly, what is the distinction between the Post Office Directory and the Telephone Directory? In the former, for the last 20 odd years, my name, in conjunction with most of my fellows, has appeared in the "commercial" section as "Ophthalmic Surgeon," with telephone number and address; also in the "trades" section, under the heading of "Surgeons: Ophthalmic." I have not looked at a Post Office Directory for many years, and being out of town I cannot at present refer to one; but at the time when my name first appeared there, most of the well-known ophthalmic names were on the list.

In old days, "ophthalmic surgeons" and "aurists" were, I think, the only two specialists advertised, but there may be other headings now. We had to pay 5s. for the insertion in the "trades" section, and for some time I refused, feeling that it was nothing but pure advertisement. But when I found that nearly all the leading ophthalmic men, from the President of the Ophthalmological Society downwards, had their names in, I felt it useless to protest, and followed suit. Now, the 5s. payment has been dropped, but my name still appears. As to the value of the advertisement, it appears to be nil; at least, I have no knowledge of ever having had a patient through the Post Office Directory.

As regards your other point: Why pay a guinea? Years ago, in the days of the old telephone company, I suggested to them that it would be a great convenience to have a medical section of the Telephone Directory. They thanked me for the suggestion, but were not prepared to face the expense. Well, if a progressive telephone company would not face the expense, how much less will a government department, which can only run the telephone at a loss?

To a great extent the Telephone Directory has become one's address-book, and to be left out may cause trouble and loss, as I have recently found to my cost, my name having been omitted in error from the last issue. The proposed addition would be a great convenience for purposes of cross-reference, but as a positive advertisement it would have no value.

I am, Sir, yours faithfully,

RAYNER D. BATTEN.

Wimpole-street, W. (Mayfair 4353), Sept. 6th, 1920.

GUINEA-PIG OR CAVY.

To the Editor of THE LANCET.

SIR,—In your last issue (p. 546) Professor H. B. Day, in describing some inoculation experiments, says that fluid was injected into "guinea-pig (A)," and later "half was injected into pig (B)." What did he actually do? Was the second animal a real pig, a hog, or was it, as appears most likely, a second guinea-pig? One may bear with resignation, if without much cheerfulness, the cheery enthusiasm which translates the inoculation of experimental animals into "pumping bugs into bunnies," and the like, so long as it does it in decent privacy in the laboratory. But when you, Sir, connive at the registration of such loose talk in a medical journal, I think it is time to make some protest. A pig is one thing and a guinea-pig is another, and if bacteriologists are not sufficiently grateful to the latter animal to give it its proper name, I would suggest that "cavy" might be made more general. It was, I think, Linnæus who said, "Nomina si nescis perit et cognitio rerum."

I am, Sir, yours faithfully,

Branscombe, Sept. 12th, 1920.

A. E. BOYCOTT.

VOLUNTARY HOSPITALS AND THE SPIRIT DUTY GRANT.—We understand that the Ministry of Health and the Scottish Board of Health are prepared to receive applications from voluntary hospitals for grants in respect of payment of duty involved by the use of duty paid spirit or drugs containing duty paid spirit for medical and surgical purposes. Forms of application have been sent to those hospitals to which a grant was paid last year. Any other hospital which desires to make application should communicate immediately with the Secretary to the Ministry of Health, Whitehall, London, S.W.1, or the Secretary to the Scottish Board of Health, Edinburgh, as the case may be.

Medical News.

UNIVERSITY OF LONDON.—A course of four lectures on Aids to Study will be given at University College by Dr. Charles E. Pearman, Grote Professor of Mind and Logic in the University of London, member of the Faculty of Medicine, on Tuesdays, at 5 P.M., beginning on Oct. 12th. The course is designed for first year students only, and will embody some practical results of psychological work with regard to learning and memorising.

UNIVERSITY OF PARIS.—A psychological institute is about to be established under a council of directors consisting of the following five professors—MM. H. Delacroix, G. Dumas, P. Janet, H. Piéron, and E. Rabaud, associated with the deans of the Facultés des Lettres et des Sciences, MM. F. Brunot and F. Houssay. The institute will undertake the practical and theoretical teaching of all branches of psychology—physiological, experimental, pathological, comparative, and general. The institute of pedagogy, founded last year, will be attached to the institute of psychology, of which it will form a section. The diploma course will consist of two terms, and, moreover, research can be carried out in the laboratories of the institute, under the supervision of the professors, in preparation for university degrees. Applications for admission should be sent any time after Oct. 15th to the Bureau des Renseignements de l'Université de Paris, at the Sorbonne.

EPSOM COLLEGE PENSIONS AND SCHOLARSHIP.—The Council of Epsom College will shortly award several France pensionerships of £30 a year to aged medical men in reduced circumstances; also a Home scholarship of £30 a year to the necessitous orphan daughter of a medical man who was for not less than five years in independent practice in England or Wales. Particulars can be obtained from the secretary of the College, 49, Bedford-square, London, W.C.1.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC.—A two months' post-graduate course in neurology will be held, starting on Oct. 4th. The fee for the course will be £7 7s., but holders of the Fellowship of Medicine ticket will be admitted free. Further particulars will be announced in our Medical Diary in a future issue.

INDUSTRIAL WELFARE SOCIETY.—The first lecture conference for welfare supervisors is being held at Balliol College, Oxford, from to-day (Friday) until Sept. 20th. The men attending are engaged in welfare work in industries of every kind. On Saturday, at 4.30 P.M., Mr. B. Muscio lectures on Industrial Psychology, and on Sunday, at 11 A.M., Dr. E. Halford Ross deals with Health in Industry. The secretary of the conference is Mr. C. Cullen, who may be addressed at Balliol College.

ORTHOPÆDIC CENTRE AT NEWCASTLE.—The orthopædic extension of the Royal Victoria Infirmary, which has actually been in occupation for some time, was formally opened on Sept. 9th by the Duke of Northumberland. The institution is fitted with all modern appliances and apparatus, including X rays, various forms of baths, and curative workshops; these include shops for carpenters, basket-makers, hairdressers, watchmakers, engineers, blacksmiths, and bootmakers, as well as printing and stencilling departments. The new buildings occupy 15 acres and have cost £160,000, of which £12,000 has still to be raised; there is accommodation for 500 in-patients, and the out-patients number well over 1000.

LECTURES ON INFANT CARE.—The National Association for the Prevention of Infant Mortality and for the Welfare of Infancy announce a special course of lectures on Infant Care for health visitors, nurses, teachers, and infant welfare workers to be held in the lecture theatre, University College, Nottingham, from Sept. 20th to 24th inclusive. Two lectures will be given each day, and the lecturers will include Dr. J. Sim Wallace, Dr. H. C. Cameron, Dr. J. W. Ballantyne, Lady F. Barrett, M.D., Dr. G. Margaret Dobrashian, and Miss J. Halford. The association announce also a course of elementary lectures on Infant Care, for infant welfare workers, teachers, and mothers, to be held at Morley Hall, George-street, Hanover-square, London, W.1, on Mondays at 6-7 P.M., from Sept. 27th to Dec. 13th. Under the joint auspices of this association and of the National Society of Day Nurseries a course of advanced lectures on Infant Care, especially intended for *crèche* nurses and probationers, will be held at Essex Hall, Essex-street, Strand, London, W.C.2, on Thursdays, at 7.30 P.M., from Sept. 30th to Dec. 16th. Tickets for all three courses of lectures at 10s., 7s. 6d., and 10s. respectively can be obtained from Miss J. Halford at 4, Tavistock-square, London, W.C.1.

MEDICAL WOMAN MAGISTRATE.—Dr. Janet E. Lane-Claypon, Dean of the Household and Social Science Department, King's College for Women, has been made a justice of the peace for the County of London.

LORD HAIG'S DISABLED OFFICERS' FUND.—Lord Haig's appeal to sportsmen has already met with considerable success. That cricketers have not been slow to respond is testified by the exciting match at the Oval, which commenced on Monday last, between the Champion County and the Rest of England, when half the proceeds were given to the Fund. The big match on the Chelsea ground is evidence that football is doing its share and other sections of sport are contributing their quota.

Mr. Henry J. Taylor, honorary ophthalmic surgeon to the Bolton Infirmary, was presented at Preston, on Sept. 14th, with the Royal Humane Society's certificate on vellum for an attempt to rescue a man who had thrown himself into the flooded Ribble. Mr. Taylor, who is 55 years of age, dived in fully clothed, but his retriever dog followed and clung to his coat, preventing him from reaching the man, who was drowned.

ST. BARTHOLOMEW'S HOSPITAL AND COLLEGE.—The old students' dinner will take place in the Guildhall, and not in the Great Hall of the Hospital, as previously notified. This alteration has been made owing to insufficient accommodation. Other arrangements remain the same as announced in our issue of Sept. 4th.

ST. BARTHOLOMEW'S HOSPITAL NURSES' HOME.—The plans of building for Queen Mary's Home for nurses in training at St. Bartholomew's Hospital have been approved and the first block is to be commenced at once. The cost of a room and all that goes with it is £350, and certain rooms have already been named according to the wish of the subscribers. Special features of the proposed home include a separate bedroom for each nurse, a lecture theatre, a library, recreation rooms, numerous bath and shampoo rooms. The present amount of the fund is £100,000 and an equivalent sum is still required. Contributions should be sent to Mr. W. McAdam Eccles, at St. Bartholomew's Hospital, London, E.C. 1.

THE LATE DR. RUTHERFOORD HARRIS.—On Sept. 2nd Dr. Frederick Rutherford Harris died at Eastbourne at the age of 64. Son of a judge in Madras and educated at Leatherhead Grammar School and abroad, he studied medicine at Edinburgh University, qualifying M.R.C.S. Eng. in 1889 and L.R.C.P. Lond. in the following year. For a while he practised medicine in Kimberley. He then became associated with Cecil Rhodes, who appointed him secretary of the British South Africa Company. South African and later home politics then became his chief interest, combined with sport of all kinds. He was Member for Kimberley in the Cape Parliament, and in 1903 was returned to the House of Commons as Member for Dulwich, sitting there for three years. Even when politics brought him constant trouble and disappointment he never returned to the practice of his profession, but led a retired life for some years before his death.

Medical Diary.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN, Hunter-street, Brunswick-square, W.C.

Post-Graduate Course on Venereal Diseases for Medical Women.

A Course arranged by the London (Royal Free Hospital) School of Medicine for Women, the Royal Free Hospital, the Elizabeth Garrett Anderson Hospital and the London Lock Hospital, for the instruction of qualified medical women in the Treatment of Venereal Diseases. The Course will extend over two weeks.

MONDAY, Sept. 20th.—5 P.M., Mrs. Rorke, M.B.: Out-patient Cliniques for Women and Children (at the Royal Free Hospital, Gray's Inn-road).

TUESDAY.—9.30 A.M., Injections (at the London Lock Hospital, 283, Harrow-road, W.) 2 P.M., Mr. C. Gibbs: Lecture and Visit to Wards (at the London Lock Hospital, Harrow-road). 6.30 P.M., Dr. Ruth Balmer: Out-patient Cliniques for Women and Children (at the Elizabeth Garrett Anderson Hospital, 144, Euston-road, N.W.).

WEDNESDAY.—9 A.M., Dr. Morna Rawlins: Visit to Maternity Wards and Labour Department (at the London Lock Hospital, Harrow-road). 11 A.M., Dr. Mary Schofield: Pathological Demonstrations (at the Royal Free Hospital). 3.30 P.M., Mr. J. E. Lane: Lecture and Visit to Wards (at the London Lock Hospital, Harrow-road).

THURSDAY.—9.30 A.M., Mrs. Rorke, M.B.: Visit to Venereal Disease Hostels. 2 P.M., Mr. J. E. R. MacDonald: Lecture and Visit to Wards (at the London Lock Hospital, Harrow-road). 5 P.M., Mrs. Rorke, M.B.: Injections (at the Royal Free Hospital).

FRIDAY.—10 A.M., Mrs. Rorke, M.B.: Treatment Ante-natal Cases (at the Royal Free Hospital). 5 P.M., Mr. J. J. Abraham: Injections and Out-patient Clinique for Women and Children (at the London Lock Hospital, 91, Dean-

street, W.). 6.30 P.M., Dr. Ruth Balmer: Out-patient Cliniques for Women and Children (at the Elizabeth Garrett Anderson Hospital).

SATURDAY.—9.15 A.M., Injections (at the Elizabeth Garrett Anderson Hospital).

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Sept. 20th.—2 P.M., Mr. B. Harman: Eye Department. 2 P.M., Mr. MacDonald: Surgical Out-patients.

TUESDAY.—10 A.M., Dr. McDougal: Electrical Department. 2 P.M., Dr. T. Gray: Surgical Out-patients.

WEDNESDAY.—2 P.M., Dr. Owen: Medical Out-patients. 2 P.M., Mr. Addison: Operations.

THURSDAY.—2 P.M., Dr. G. Stewart: Medical Out-patients. 2 P.M., Mr. MacDonald: Surgical Out-patients.

FRIDAY.—2 P.M., Mr. Banks Davis: Diseases of the Throat, Nose, and Ear. 2 P.M., Dr. Pernet: Skin Department.

SATURDAY.—2 P.M., Dr. Owen: Medical Out-patients. 2 P.M., Mr. Sinclair: Surgical Out-patients.

Daily.—10 A.M., Ward Visits. 1 P.M., In-patient, Out-patient Clinics and Operations.

MALE LOCK HOSPITAL, Dean-street, W.

MONDAY, Sept. 13th, WEDNESDAY, AND FRIDAY.—5 P.M., Dr. C. Russ: Demonstration of the Treatment of Gonorrhoea by Electrolysis.

MANCHESTER FRENCH HOSPITAL POST-GRADUATE LECTURES, 24, Acomb-street (behind Whitworth Park).

THURSDAY, Sept. 23rd.—4.15 P.M., Dr. A. C. Magian: Tubal Abortion.

Appointments.

BREWER, D., M.R.C.S., L.R.C.P. Lond., D.P.H., has been appointed Medical Officer of Health for the Borough of Swindon.

BROADFOOT, J., M.B., Ch.B. Glas., Certifying Surgeon under the Factory and Workshop Acts for Dingwall.

MAYLARD, A. E., M.B., B.S. Lond., one of the Medical Referees under the Workmen's Compensation Act, 1906, for the Sheriffdom of Lanark.

TANNER, W. E., M.S., F.R.C.S., Assistant Surgeon to the Prince of Wales's General Hospital, Tottenham.

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary.—Jun. M.O. £500.

Abergavenny, Monmouthshire Asylum.—Jun. Asst. M.O. £300.

Ayrshire Sanatorium, Glenafton, New Cumnock.—Res. Asst. £250.

Barnsley, Beckett Hospital and Dispensary.—Sen. H.S. £250.

Barrow-in-Furness, North Lonsdale Hospital.—Sec. Res. H.S. £225.

Battersea General Hospital (Incorporated), Battersea Park, S.W.—

Third Res. M.O. £200.

Bedford County Hospital.—Asst. H.S. £150.

Bethnal Green Infirmary, Cambridge-road, Bethnal Green, E.—

Two Jun. M.O.'s. £400.

Birmingham General Hospital.—Surg. Registrar. £200.

Brighton, Royal Sussex County Hospital.—Jun. H.S. £150.

British Guiana.—Asst. M.O.H. £600.

Carnegie Dunfermline Trust.—Asst. M.O. £500.

Central London Ophthalmic Hospital, Judd-street St. Pancras.—

H.S. £100.

Chesterfield and North Derbyshire Royal Hospital.—Jun. H.S. £250.

City of London Hospital for Diseases of the Chest, Victoria Park, E.—

H.P. £100. Also Tuberc. O. £600.

Colchester, Essex County Hospital.—H.S. £200.

Colonial Service.—M.O.'s for West African Medical Staff, Govern-

ment Service in Malaya, East African Protectorates, West Indies

(including British Guiana), Fiji, and the Western Pacific, &c.

Coventry and Warwickshire Hospital, Coventry.—Hon. P.

Derby Borough Mental Hospital.—Asst. M.O. £350.

Derby, Derbyshire Royal Infirmary.—Asst. H.S. and Cas. O. £200.

Devonport, Royal Albert Hospital.—H.S. £200.

Durham University College of Medicine, Newcastle-upon-Tyne.—

Lecturer on Med. Jurisprudence.

East Africa.—M.O. to C.M.S., Kavirondo.

Eastbourne, Princess Alice Hospital.—Res. M.O. £175.

East London Hospital for Children and Dispensary for Women,

Shadwell, E.—H.S. and H.P. £125.

Egyptian Government, School of Medicine.—Prof. of Pharmacology.

L.E. 1,200-1,440. Lecturer in Anat. L.E. 720.

Glamorgan County Asylum, Bridgend.—Jun. Asst. M.O. £350.

Glasgow District Mental Hospital, Gartloch, Gartcosh.—Asst. M.O.

£350.

Heywood Borough.—M.O.H. £600.

Hospital for Sick Children, Great Ormond-street, W.C.—Cas. M.O.

£200. Also Asst. Cas. M.O., H.S., and H.P. £50 each.

Huddersfield Royal Infirmary.—Asst. H.S. £150.

Hull City Asylum, Witherby, near Hull.—Jun. Asst. M.O. £300.

Hull Royal Infirmary.—Asst. H.S. £150.

Ingham Infirmary and South Shields and Westoe Dispensary.—

Jun. H.S. £175.

Johannesburg, South African School of Mines and Technology.—

Professorship of Vet. Anat. £860.

Kenington Board of Guardians Infirmary, Marloes-road.—Patho-

logist. £300.

Lancaster County Asylum.—Asst. M.O. £300.

Leeds City.—Asst. M.O. £500.

Leicester Royal Infirmary.—H.P. £200. Also Res. Anesth. £250.

Lincoln County Hospital.—Jun. H.S. £150.

Liverpool Royal Infirmary.—H.P.'s, H.S.'s, and Sen. Cas. O. £60 each.

Macclesfield General Infirmary.—Res. H.S. £200.

Maidstone, Kent County Mental Hospital.—Jun. Asst. M.O. £300.

Maidstone, Kent County Ophthalmic Hospital.—H.S. £300.

Maidstone, West Kent General Hospital.—Two H.S.'s. £220.

Manchester, Ancoats Hospital.—Res. Surg. O. £250.

Manchester Northern Hospital for Women and Children, Park-place, Cheetham Hill-road.—H.S.
 Manchester, St. Mary's Hospitals for Women and Children.—H.S. for Whitworth Park Hospital. £100.
 Manchester Royal Infirmary, Central Branch, Roby-street.—Res. M.O. £250.
 Margate, Princess Mary's Hospital for Children, Cliftonville.—Jun. Asst. M.O. £515 6s.
 Metropolitan Asylums Board Infectious Hospitals Service.—Jun. Asst. M.O.'s. £515 6s.
 Middlesbrough Education Committee.—Sch. Dent. £400.
 Ministry of Pensions, London Region.—Med. Referee (Marylebone Borough).
 National Hospital for Diseases of the Heart, Westmoreland-street, W.—Out-patient M.O. £150.
 National Hospital for the Paralysed and Epileptic, Queen-square, Bloomsbury, W.C.—Registrar. £200. Also Sen. H.P. £150.
 Newcastle-upon-Tyne City Mental Hospital, Gosforth.—Sen. Asst. M.O. £500.
 Northampton General Hospital.—H.S. £200.
 Nottingham City Education Committee.—Jun. Asst. Sch. M.O. £500.
 Pontypridd Urban District Council.—Female Asst. M.O. £550.
 Prince of Wales's General Hospital, Tottenham, N.—H.P. and H.S. £200. Jun. H.S. and Jun. H.P. £120.
 Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—H.S. £100.
 Reading, Royal Berkshire Hospital.—H.P. and Second H.S. £200 each.
 Royal London Ophthalmic Hospital, City-road, E.C.—Asst. M.O., Department for Venereal Diseases. £1 ls. a session.
 St. Mary's Hospital, Paddington, W.—Res. Asst. Anæsth. £100.
 Salford Royal Hospital.—Res. Surg. O. £250. H.P. £200. H.S., Jun. H.S., and Cas. H.S. £150 each.
 Scarborough Hospital and Dispensary.—Two H.S.'s. £150.
 Sheffield Royal Hospital.—Asst. Cas. O. £150.
 Sheffield Royal Infirmary.—H.S. for Ear, Nose and Throat. £150.
 Sheffield University, Department of Pathology and Bacteriology.—Director. £800. Asst. Director. £500. Curator of Path. Museum. £600.
 Southampton County Borough.—Asst. M.O.H. £500.
 Sydney University, New South Wales, Australia.—Chair of Dentistry. £1100. Also Chair of Physiology. £1150.
 Taunton and Somerset Hospital.—Jun. H.S. £150.
 Uganda.—M.O. to C.M.S. Mengo Medical School.
 Wakefield, Clayton Hospital.—Sen. H.S. £250. Also Jun. H.S. £200.
 West Hartlepool, Cameron Hospital.—H.S. £300.
 Westmorland Sanatorium and Home, Meathop, Grange-over-Sands.—Res. Asst. M.O. to the Westmorland Sanatorium and Asst. Tuberc. O. for Westmorland. £350.
 Winchester, Royal Hampshire County Hospital.—H.S.
 Wolverhampton and Staffordshire General Hospital.—H.S. £200.
 Woodilee Mental Hospital, Lenzie, near Glasgow.—Asst. M.O. £350.
 Worcester County and City Mental Hospital, Powick.—Jun. Asst. M.O. £350.
 Worcestershire County Council.—Sch. Oculist. £500.
 The Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Heckington, Chryston, and Staines.

Births, Marriages, and Deaths.

BIRTHS.

ALDRIDGE.—On Sept. 9th, at Magdalene House, Glastonbury, Somerset, the wife of Dr. F. J. Aldridge, of a son.
 BUNBURY.—On Sept. 7th, at Highfield, Colsterworth, the wife of E. G. Bunbury, M.R.C.S., L.R.C.P., of a son.
 GOODE.—On Sept. 10th, at Bootham, York, the wife of Henry Norman Goode, M.C., M.B., F.R.C.S.E., of a son.
 KIRK.—On Sept. 4th, at Treton House, Bellingham, Northumberland, the wife of Dr. G. W. L. Kirk, of a daughter.
 MALONE.—On August 21st, in a Nursing Home, Belfast, the wife of Surgeon Lieut.-Comdr. A. E. Malone, M.B., B.A., Royal Navy, of a daughter.

MARRIAGES.

CONOLEY—COWAN.—On Sept. 9th, at Marlborough House, Glasgow, Oliver Francis Conoley, M.R.C.S., L.R.C.P.; London, to Isobel Margaret, daughter of Jas. N. Cowan, Mount Florida, Glasgow.
 HILL—FORTUNE.—On Sept. 7th, at St. John's, Dumfries, Dr. James Gill Hill, M.C., to Julia Violet McNaghten, youngest daughter of Mr. and Mrs. J. Fortune, of Bengaim, Kirkeudbrightshire.
 JEPSON—SCOTT.—On Sept. 7th, at St. Mark's, Surbiton, Captain W. Baly Jepson, M.C. (late R.A.M.C.), to Jean Margarita, only surviving child of Mr. and Mrs. R. A. Scott, of Cathay, Surbiton.
 MCFADYEAN—McCORMICK.—On Saturday, Sept. 11th, at Holy Trinity Church, Haverstock-hill, N.W., Kenneth McFadyean, M.R.C.S., L.R.C.P., to Elsie, youngest daughter of Mr. and Mrs. W. A. McCormick, Windermere-avenue, Finchley, N.
 WATSON—CHARRINGTON.—On Sept. 8th, at St. Bartholomew's, Leigh, Surrey, Lieutenant-Colonel John W. Watson, C.I.E., I.M.S., to Ruth Mary, daughter of the late Ernest Charrington, and Mrs. Wilfred Hadley, Parkside, Reigate.

DEATHS.

BARTIE.—On Sept. 11th, very suddenly, at Knocke-sur-Mer, Belgium, Lieutenant-General Sir William Bartie, V.C., K.C.B., K.C.M.G.
 GUINNESS.—At Nairobi, British East Africa, Wyndham Malan Grattan Guinness, M.D.
 JOHNSON.—On Sept. 12th, in London, Obadiah Johnson, M.D., of Marble Hall, Lagos, Nigeria, aged 71 years.
 TEEVAN.—On August 20th, at Upper Grosvenor-road, Tunbridge Wells, Henry Teevan, M.R.C.S. Eng., L.S.A., formerly Captain, 75th (Stirlingshire) Regiment.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

THE UNIVERSITY PROBLEM.¹

BY SIR EDWARD SHARPEY SCHAFER, F.R.S.

To keep up with the times a university must constantly expand. The mediæval university merely needed intellectual expansion. But the time is past when a university could be physically constituted out of a library and lecture rooms. It is chiefly the extensions imposed upon the universities by the teaching of the natural sciences which necessitate their physical expansion, and we have to consider how such expansion is to be effected. The particular difficulty in providing for the requirements of the natural sciences is the furnishing of adequate laboratory accommodation.

The members who constitute the governing bodies of most universities appear unfortunately unable to appreciate the fact that the university will have a far longer life than its individual members. University buildings are usually so constructed as to be incapable of extension. And in consequence of this lack of foresight a laboratory which has seemed, and perhaps has been, adequate for its purpose at the time of its construction will in the course of 20 years become inadequate. Plans for new buildings are generally drawn up in such a manner that future expansion is barred. So that the problem of adequate provision presents itself again in a few years, when with proper prevision it might have been settled for many years.

The Ideal Environment.

The idea is unfortunately prevalent in this country that universities should be situated in large cities, but the ideal environment of a university is an Academia—a place for undisturbed work and quiet contemplation, whence the sights and sounds of the city are excluded—not a site in the middle of the town with traffic rumbling past, surrounded as often as not by slums and squalor, by dirty streets with cheap lodging-houses, with music halls and movies in convenient proximity; but with hardly a yard of ground in possession beyond that to be covered by the buildings, and with the possibility of expansion only at enormous cost. If the situation chosen is in a prominent situation the building must have a handsome elevation, increasing the cost hugely whilst generally diminishing its value for the purpose for which it is erected. Is it any wonder, when such large sums have to be paid for site and building, that but little is left for equipment and brains?

Take, for example, the University of London—now University College. About a century ago it occurred to a few people that a university education should be available to any member of the community, whatever his opinion on religion, who might be able to take advantage of the educational privileges offered. A large sum of money was collected, and the site selected was little more than a mile from Charing Cross. Though with the money at their disposal the promoters of the new university might have bought a couple of hundred acres, and still have had money enough for all the building required, they bought a comparatively small plot of land and spent the greater part of their money in erecting an incomplete edifice, provided with a fine dome and portico, but lacking the endowments which are needed to attract and keep the best scholars. Their unwise example has been followed everywhere. No founders of universities in this country realise that every university will need unlimited room for expansion, and that this can only be obtained by the acquisition of land on a large scale at the time the university is founded. The difficulty of getting it later may be insuperable, as, indeed, the attempts to extend the University of London have abundantly shown. One of the present schemes for its expansion contemplates the acquisition of a large area in the neighbourhood of the British Museum, covered with streets and houses. Its carrying out would involve the expenditure of many millions of money, and would only then provide for immediate necessities; in 50 or 100 years far more space will be wanted. The sum needed to promote such an undertaking would be sufficient to provide at least four university centres for London, provided they are set down where an adequate amount of land can still be purchased at a reasonable expense. Why London, with its permanent population of 7 millions and its large floating population, should not have as many universities or university centres as Scotland or Sweden, or more than Ireland or Norway, or Yorkshire—all with smaller populations—is a question which can be rightly answered only in

¹ Abridged from an address delivered at Cardiff to the Medical School of the University College of South Wales.

one way, although up to the present the reply has not taken the direction that common sense would indicate. The longer London waits the further must its universities go afield and the greater will be the cost of establishing them.

The Acquisition of Land.

The extreme difficulty of providing sufficient land for expansion within the limits of a city was shown in the experience of Edinburgh University, where a site was secured in the neighbourhood of the existing university building which was found inadequate almost at once on completion of the building. The need for further accommodation has of late assumed an acute form, and further provision for the medical sciences is again urgently demanded. Steps have been taken to obtain a site on which to erect a Lister Institute. For this site, of about two and a half acres, covered by tenement houses, which must be removed before it can be utilised, the large sum of £55,000—about £22,000 an acre—has to be paid; it is estimated that the buildings to be accommodated upon it will cost nearly a quarter of a million of money, and to judge from past experience, the necessity for further expansion will arise before the institute has been long occupied. This will only provide for a single subject. There are many others which are crying out just as loudly for expansion, and to meet their demands a site comprising many acres will soon have to be found.

Fortunately for the future of Edinburgh, the present head of the university has been able to look into the future further than his predecessors, and has persuaded the governing body to purchase a plot of land of about 115 acres on the outskirts of the city, little more than a mile from the existing university, and easily accessible even by present means of conveyance. The site is admirably adapted for a university park or campus with abundance of space for buildings. It will furnish room for an amount of expansion which is not likely to be overtaken within at least the next hundred years. The cost of acquiring this large area of land is little more than half that needed to obtain the two and a half acres wanted for the Lister Pathological Institute. And the transference to it of all laboratories which are not immediately related to clinical work can, in view of the site difficulties within the city itself, only be a question of time. Nor is there any reason why a university hospital should not be one of the laboratories to be erected upon it. For a hospital is, in fact, a laboratory, in which the experiments which nature or accident make upon the human subject are utilised for the treatment and study of disease. Doubtless a large sum of money would be required to carry out the scheme in its entirety. But it will not cost half as much as an attempt to continue the present system, and when the benefits which will accrue are realised there should be little doubt as to which policy will ultimately prevail.

The longer the delay in acquiring land near a growing town the less can be acquired and the more must be paid. Compare the relative values just given. Two and a half acres of town land for £55,000, and 115 acres a short distance away for £28,000. In fifty to a hundred years' time this 115-acre plot would also, under ordinary circumstances, have become town land and have been covered with houses; and even at the present rate for town land the cost would then be more than 2½ million pounds!

I have mentioned this matter because, although the acquisition of a large area of land for university buildings is not only a common but even a constant feature in the United States, this is, so far as I know, the first time the principle has been adopted in our own country.

Every university should have enough land for all purposes. Even 100 acres may not suffice for the university buildings alone. Cornell, founded little more than 50 years ago, already finds a campus of this size inadequate. Besides lecture-rooms and laboratories provision should be made for students' hostels, for athletic grounds, for professors' and lecturers' houses. A university so planned would be self-contained—a small city in itself—within which not only means for instruction, but also for recreation and amusement are provided.

That the university ought to possess more land than even its own probable future necessities is indicated by the fact that the planting of such an institution in a spacious park tends to stimulate the erection of good houses in its neighbourhood and raises the value of the land around it. Why should not the university have the benefit of this rise in value instead of the speculative builder?

The above considerations render it obvious that a university should acquire, while it can be acquired, enough land not only for present but for all future needs.

The question of site is intimately bound up with the style, arrangement, and cost of the buildings to be erected on it. If the university is free to build laboratories on its own land a simpler and less expensive style of architecture can be adopted, and, moreover, it is unnecessary to provide high buildings; each department can be self-contained, easily capable of extension, and abundantly lighted.

The Advantages of Temporary Buildings.

Not the least advantage of the possession of a campus is the freedom it gives the university to put up temporary buildings, a very real advantage when there is difficulty in obtaining large sums of money. But the advantage of a temporary building is not alone that of economy. Probably no building was ever yet constructed, however carefully, in which it was not found that mistakes had been made which could only be set right with difficulty and expense. In many cases the work and teaching of a new professor has been seriously hampered by having to be carried on in a laboratory designed by his predecessor. There is much to be said, therefore, for the erection, in the first instance, of buildings of a temporary character—so constructed, however, that they may be used with advantage for 50 years or more. There is no laboratory in the world, however expensive and magnificent its construction, which will not be antiquated in the course of 50 or 60 years. Thus, seeing that it can be easily replaced at a relatively small cost, a temporary building may serve its purpose even better than a professedly permanent structure.

The Problems of Expansion.

The crux of schemes for extension is the problem as to whether a university should welcome all who desire to receive instruction within its walls, or should impose a limit upon the number it is willing to admit. It will surely be a calamity if our universities are compelled to refuse admission to genuine students. But it will be a greater calamity to admit them and provide inadequately for their instruction.

Again, by no means the least part of the subject of university expansion concerns facilities for research. Universities were no doubt originally established for teaching, but it is universally recognised that if a high standard of teaching is to be maintained this must go hand in hand with the pursuit of new knowledge. With the growth of science and medicine the necessity is more than ever imperative, and the encouragement of original investigation is to be looked upon as a university function not less important than the imparting of information.

Lastly arises the all-important question of finance. How is the money for university expansion to be provided? For it must be admitted that no university can be self-supporting. There should be no hesitation about the answer: A university education ought to be provided by the State for all who are capable of benefiting by it. Elementary and secondary teaching are already so provided; why make an exception for the highest grade? The benefit of elementary and secondary education is mainly individual: the indirect benefit to the community which is often assumed to result from it is problematical. But education of a university character is an asset of direct value to the community. No elaborate argument is required to prove this. All important progress in science, whether in manufactures, in means of communication, in naval and military matters, in engineering, in medicine, has been the result of purely scientific researches carried on for the most part in universities or in colleges of a university standard. It is therefore not only the duty but the interest of the State to maintain universities in full efficiency. But no statesman in our country has ever recognised this duty or attended to this interest.

If there could be found a statesman to treat the question of providing for the needs of the universities, not in a niggardly manner or as if it were a question of charity, but as a sound business proposition of direct benefit to the State, how much better a chance should we have not only of maintaining our own material position, but, which is yet more important, of contributing our proper share to the sum of human knowledge and thereby ministering to the happiness and prosperity of mankind!

COLONIAL HEALTH REPORTS.

Leprosy in Rodrigues.

RODRIGUES or Rodriguez is a coral island of 42 square miles extent and with less than 2000 inhabitants, situated in the Indian Ocean some 350 miles east of Mauritius. In a report, submitted by Dr. S. E. Mangenie to the Medical and Health Department of Mauritius, he says there is no doubt that leprosy was introduced into the island by a man known as "Diango," who came from Mauritius about 40 or 50 years ago. Diango, who was employed as a fisherman by a family residing at Oyster Bay, a small coast settlement, developed leprosy four or five years later and went to reside up the mountain. A year or so after his departure one of the sons of his employer, who used to fish with him in the same boat, became affected with the disease and from this one and only source of contagion the disease gradually made its appearance in other families, all residents of Oyster Bay. Dr. Mangenie is aware of 23 cases of leprosy, 16 of which are the descendants, directly or through marriage, of the first family affected with the disease. The other 7 cases are scattered over the island and these sufferers

are the descendants of Diango. During the last seven years four or five deaths due to leprosy have been registered and about nine new cases have come to light. Dr. Manganie suggests that a scheme for proper and strict isolation should be put in force.

Straits Settlements.—The estimated population of the colony in 1918 was 827,719. The birth-rate decreased from 30.7 in 1917 to 28.6 per 1000 in 1918. The death-rate, on the other hand, increased from 37.0 per 1000 in 1917 to 43.9 in 1918. The principal causes of death in the latter year were malaria (4783 cases), infantile mortality (6009), influenza (3500), tuberculosis (2536), beri-beri (1961), and dysentery (1362). Dangerous infectious diseases notified in the colony during the year caused 55 deaths from small-pox, 68 from cholera, and 204 from plague, the corresponding figures in 1917 having been 176, 9, and 44. An outbreak of beri-beri in the prisons was traced to prisoners having been fed on rice steamed under pressure. After the cause had been ascertained and rectified there were practically no fresh cases.

Leeward Islands.—In his report on the Blue-book Mr. F. H. Watkins, acting Colonial Secretary, states that in Antigua the estimated population on Dec. 31st, 1918, was 31,179. The births registered in 1918 numbered 1169, being 37.5 per 1000. The legitimate births were 295 and the illegitimate 874. The death-rate was 31.6 per 1000. The deaths of children under 1 year, exclusive of stillbirths, were 20.3 per cent. of the total. In the Presidency of St. Kitts-Nevis the estimated population at the close of 1918 was 27,047 in St. Kitts, 12,254 in Nevis, and 4878 in Anguilla. The birth-rates were in St. Kitts 34.6 per 1000, in Nevis 38.1, and in Anguilla 33.2, whilst the death-rates were—St. Kitts, 28.7 per 1000, Nevis 25.0, and Anguilla 17.7. The mortality of infants under 1 year of age was 300, 284, and 133 per 1000 of the total death-rate in St. Kitts, Nevis, and Anguilla respectively. In Dominica the estimated population was 40,270; the birth-rate was 36.7 per 1000 and the death-rate 28.0. The illegitimate births were in excess of the legitimate. Montserrat had a population in 1918 of 11,264; the birth-rate was 35.9 and the death-rate 19.1 per 1000. The general health of the colony was satisfactory, but, the report adds, "No great advance will be made in health and sanitary conditions until the people as a whole are brought to realise the importance of cleanliness in elementary habits, and of ventilation and a well-regulated diet, especially for infants."

BRISTOL HOSPITAL SUNDAY FUND.

THE Lord Mayor of Bristol has collected this year a total of £6028 6s. 9d., and has thus exceeded all previous collections by more than £900. Approximately half the money came from places of worship, and the remainder from schools, athletic clubs, and various sources. The fund is gradually assuming a place of importance among the various sources of hospital income, though at present it covers only a small fraction of the hospital expenditure of the city.

RHEUMATISM AND STAMMERING.

IN a recent report submitted to the Education Committee of the London County Council on the classes for the remedial treatment of stammering children, established in January, 1920, it was noted that boy stammerers outnumber girl stammerers in at least the proportion of 3 to 1. In a class held at Brixton the medical officer pointed out that of 7 children in whom the stammering developed after the age of six, 6 were cured. Two of these cases were ascribed to fright, 2 were imitative cases, and 2 came on after rheumatic fever. The common association of rheumatic fever with another disease of coördination in childhood—namely, chorea—is of course well established.

FUNCTIONAL RE-EDUCATION IN AMERICA.

DURING December, 1917, and the first half of 1918, Dr. W. Seaman Bainbridge visited Europe on behalf of the U.S. Navy Department, and subsequently his Report on Medical and Surgical Developments of the War was issued as a special number of the *United States Naval Medical Bulletin* (Washington, Government Printing Office). Dr. Bainbridge used his eyes well, and, in addition to his own vivid descriptions of his visits in England and on the continent, has included in his report brief summaries of the surgical lessons of the war from such authorities as Mr. H. S. Souttar and Professor (then Colonel) Gosset. The section on vocational training, abundantly illustrated with pictures taken in France, Belgium, and England, is perhaps of the greatest interest at the present time. Dr. Bainbridge emphasises the need of propaganda work to bring home to the general public their responsibility in caring for the permanent welfare of war cripples. He mentions that four cinema reels have been prepared to this end by the American Red Cross. To M. Edouard Herriot, the Mayor of Lyons, is given the credit for placing France at the head of European

countries in first recognising officially the work of vocational re-education. The centre at the Grand Palais in Paris is noted as a model for American centres. The fine Department of Physiotherapy which has grown up since this report was written, under the care of Commander Bainbridge himself at the Brooklyn Naval Hospital, no doubt owes much to the inspiration of the earlier French work. The author believes that functional re-education should not wait for wounds to heal nor vocational training until function is completely restored. He urges that if schools must be under military discipline the latter should as far as possible be camouflaged, adding, "for the men are sick of military routine and resent control." The centres should be made home-like and attractive.

A HYGIENIC TRUSS PAD COVER.

THE R. H. Heward Company, of Twickenham, has sent us a sample of a moulded rubber truss pad cover, which is certainly conducive to cleanliness and comfort. It fits snugly over the pad and is fastened by a stud button.

HINTS TO MEDICAL WRITERS.

THE New York State *Journal of Medicine* suggests rules to writers which, if carried out, would materially lighten the task and, incidentally, brighten the life of the medical editor. When the subject is selected (so the admonition runs) write or dictate everything that may be in the mind or that may occur as pertinent to it. Then do three things: First, select a definite title or a clear definite text. Write it in clear large words; set it up before you on your desk; take your paper, a good blue pencil, and mercilessly cut out everything that does not conform with the text. Ability to "follow the text" is one of the highest attributes of the human mind. Second, go over the various paragraphs that remain and arrange them in logical order. Third, go over what is then left and study each important word and select synonyms that will best express the thought in your mind.

The admonition is reminiscent of the advice received in our youth, to think before saying anything whether it was true, kind, and useful. The application of either rule would considerably reduce output.

Some Clinical Points

CONNECTED WITH

GALL-STONES.

A Post-Graduate Lecture delivered at the University of Sheffield

By ARTHUR J. HALL, M.A., M.D. CANTAB.,
F.R.C.P. LOND.,

PROFESSOR OF MEDICINE, UNIVERSITY OF SHEFFIELD.

LADIES AND GENTLEMEN,—Cholelithiasis is very common. Its treatment is, at present, entirely surgical and outside the province of clinical medicine. I shall therefore confine my remarks to some of the problems connected with diagnosis, ætiology, and prognosis, which are constantly presenting themselves to every practitioner of medicine.

It is instructive to consider how greatly the diagnosis of gall-stones has been facilitated during the last 30 years. This we owe almost entirely to abdominal surgery.

For example, I was recently asked to see a married woman of 50, who gave a typical history of biliary colic for 23 years. When I saw her it was obvious that she was suffering also from malignant disease and had a hard gland behind the left sterno-clavicular articulation. Her husband did not believe my diagnosis, as he had been told exactly the same thing 23 years before by another consultant when his wife first began to have her pain. As this consultant was still in practice it was suggested that he should be called in again and asked to bring his old notes with him. This he did and read out to us a description which nowadays would suggest a typical attack of biliary colic. Yet 23 years ago the question of gall-stones was put aside in favour of malignant disease. The patient died a few weeks later of abdominal carcinoma.

The fact is that the gall-stone complex, as we know it now, was not at that time common knowledge.

JAUNDICE NOT AN ESSENTIAL SYMPTOM.

In considering the symptoms due to gall-stones the first point I would lay stress upon is that jaundice is not, as is often supposed, an essential symptom. The anatomy of the gall-bladder and bile ducts shows that since the gall-bladder is a cul-de-sac branching off by the cystic duct from the main bile channel, there is no obvious reason why obstruction of this bile channel and consequent jaundice should occur so long as the stones remain in the gall-bladder. It is when they get out into the common bile-duct or when some catarrhal changes arise which block this channel that obstruction takes place. When present, however, jaundice is a valuable confirmation of the diagnosis.

Another point to remember about jaundice is that it is often so slight and so transient as not to be recognised even when it does occur. A full and complete yellowness of the conjunctiva and skin, known in the north of England as the "yellow jaundice," requires a certain intensity and completeness, and consequently a certain duration of obstruction. If a stone is expelled from the gall-bladder, slips back, or, being small, passes fairly quickly—say, in two or three hours—down the whole length of the common duct and out into the bowel, the obstruction to the bile flow which it produces during its passage may be insufficient to cause a recognisable deposition of bile pigment in the tissues. Inquiry, however, may show that after such an attack of pain the urine is rather highly coloured, and the patient is said to have been slightly sallow or a bad colour. These are points which should be carefully inquired into. It is also not uncommon to find a history of jaundice preceding the date of onset of pain by some years (see Postscript).

ABDOMINAL PAIN OR DISCOMFORT.

Of all symptoms abdominal pain or discomfort is the most common and the most important. Its position must first be considered. That it is usually and principally in the right upper abdomen goes without saying, and that it is by no means always limited to that region is familiar to all. Its most common direction of spread is round the body to the right and up towards the right shoulder, but it may vary in many ways. Sometimes it is quite misleading in its situation.

Thus, a man, aged 36, whom I saw in January, 1917, gave the following history. For four years he had pain between

the shoulders, which was worse on waking and relieved by getting up. For one and a half years it had been more severe round the waist, worse on walking about. In the last attack it "left the stomach and went to the shoulders and down the arms." If he put his foot on anything rough on the ground whilst in the dark it doubled him up. When I heard his statement I must admit that the question of gall-stones did not occur to me. However, the condition was diagnosed later by one of my surgical colleagues and its presence confirmed by his subsequent operation.

Such a history emphasises the wide variations in area of pain which may exist.

As to the character of the pain, there is often much valuable information to be learned. In spite of the best intention on the part of the patient, it is quite extraordinarily difficult at times to get a true picture from his statements. The proper perspective can best be got by letting the patient talk on, often at somewhat wearying length. Some chance remark by the patient or by a friend who has been present during an attack often does more in confirming the diagnosis of gall-stones than any number of direct questions. This is really a form of psychoanalysis, and thus necessarily somewhat tedious and lengthy. If there is real colic of a typical kind the difficulty is slight. If, however, it is of less severity, and especially if the patient is of the uncommunicative type so common in the north, the difficulties may be great.

A case I saw quite recently will illustrate the kind of difficulty I mean. The patient, Mrs. X, was a stout pallid married woman of about 58. The history as given to me was as follows: She had suffered from "nervous dyspepsia" for ten years off and on. Two years ago she began to be worse with some constipation. She had pain after food, which increased by taking meat, and persisted for eight or nine hours after the meal. In December, 1919, she had pain irrespective of food. It would begin about 3 P.M. and last till 6 or 7 o'clock. Hot water or a little brandy relieved it, and also artificially induced vomiting. An examination of the abdomen at that time gave no tenderness and nothing abnormal was to be felt. The site of pain was vaguely referred to the upper abdomen. She was taken into a nursing home for further investigation, but nothing definite was made out. A test breakfast showed a rather large return, with much undigested solid; no reaction to Congo-red or tropæolin. No occult blood in fæces. An opaque meal showed nothing abnormal.

At that time there was nothing elicited which pointed directly to gall-stones. I did not see her again for six weeks, during which time the pain had not been severe, until ten days before my visit, when after two simple enemata she became collapsed and her doctor thought she would die. On this visit she told us, for the first time, that she had jaundice 12 years previously and that the doctor who then saw her said it was probably gall-stones. Further inquiry showed that the attacks of pain often came on quite suddenly, when she was feeling otherwise well, that they reached a maximum soon and passed off in two or three hours, and that after an attack she was often sallow and the urine rather dark. Examination elicited distinct tenderness over the gall-bladder region. Operation was performed by a surgeon a few days later and gall-stones were removed.

The points that I should lay stress upon as regards the character of the pain are: (1) Rather sudden onset, unexpectedly at any time of night or day; (2) rapid increase to acute severity; (3) duration of a few hours; (4) sudden decline in acute severity with more gradual decline of soreness; (5) tendency to follow unusual activity; (6) occasional but not constant relation to food. This kind of attack occurring in the night is not at all uncommon. My colleague Dr. A. E. Barnes, in discussing the diagnosis of duodenal ulcer at the Sheffield Medico-Chirurgical Society last session, laid down as an important axiom that "any abdominal pain which comes on spontaneously in the night should arouse suspicion of organic disease." I agree fully with that, and in my experience it is by no means uncommon in gall-stones. I also have records of cases in which attacks have been started by the jolting of long railway or motor journeys.

Complete freedom from pain in the intervals between acute attacks is always suggestive. In many cases, however, chronic discomfort—usually called indigestion—fills up most of the intervals. Tenderness over the gall-bladder region is usually found on careful examination. It is especially marked at or about the occurrence of an attack of colic, and may be constant.

THE PATIENT'S AGE AT ONSET.

In older text-books of pathology considerable stress is laid upon the frequency with which gall-stones were found at autopsy in elderly persons who had died of other diseases, and it was assumed that these had produced no symptoms during life. Such an assumption is, I think, not warranted. From what we now know of the varied symptoms which gall-stones may produce, it seems much more likely that in most, if not all, these cases symptoms of more or less severity did occur from time to time, but that as they were probably of a dyspeptic type their true cause was not suspected. Whether a person can have gall-stones for any length of time without any symptoms at all is doubtful.¹ It does not seem impossible; for we know that they may remain latent for long periods—ten years or even more. In every case, therefore, the question naturally presents itself as to how long have the stones been there? If they can remain latent for ten years there is no *a priori* reason why they should not do so for 20 or 30 or even more years. I raise this point because I am inclined to think that we are too apt to look upon gall-stones as a disease limited to middle life or later. This is certainly the teaching of our standard text-books, and appears to be the general impression. This view was chiefly obtained from statistics of autopsies at a time before operations for gall-stones were common, and deserves reconsideration in the light of more recent knowledge. The question is one of some importance because it leads sometimes to the wrong diagnosis of severe cases of biliary colic in young people, largely because of the youth of the subject. This particularly applies to persons between 15 and 30 years of age. At any age younger than 15 one must admit that gall-stones are very rare. Still,² in 1899, was able to collect only 20 cases in children under 14 years of age. Of these, 12 were in infants under 3 months; of the remaining 8 only 2 are recorded as having had colic. In 3, stones were passed per rectum, in 4 they were found post mortem. When, however, early youth and early adult life are reached my own experience makes me think that the condition must be more common than is generally supposed, and that it leads to mistaken diagnosis.

The following cases illustrate this point:—

CASE 1.—In 1905 I was called to see a single woman (C), 22 years of age, who was said to be suffering from floating kidney with Dietl's crises. There was a history of a bicycle accident several years ago, which was said to have started the trouble, and a fall from a horse in 1904, which had made it worse. She had a large loose kidney on the right side which was tender to touch. Acute attacks of pain kept recurring without vomiting or jaundice, but accompanied by flatulent distension. The diagnosis of floating kidney seemed correct at that time, and suitable means for supporting the kidney were adopted.

I did not see her again until 1913. The attacks of what was now called "indigestion pain," but was obviously her original trouble, had kept coming on at intervals and latterly getting more severe. Inquiry showed that the pain always began to the right of the epigastrium and went up to the right shoulder and back. One night her sister found her "curled up" with pain on the bedroom floor. When I saw her she was just getting over an attack, and there was great tenderness on the slightest palpation of the gall-bladder area. The kidney could still be felt and was sensitive to pressure, but relatively to the other tenderness this was negligible. Gall-stones were diagnosed and at operation several were found—one large one impacted in the cystic duct.

In this case, then, gall-stone colic had been overlooked and called "floating kidney" for over ten years. It is probable that the stones were present before she was 20.

CASE 2.—This was a single woman (E.), 25 years of age. I was asked to see her in July, 1911, when she gave the following history. Eight years before she had an attack of what was called catarrhal jaundice—that is to say, when 17 years old. Three years ago she had her first attack of abdominal pain. This pain was in the gall-bladder region and usually came on in the night. She was found to have a movable kidney on the right, which was diagnosed as the cause of her pain. From that time to the present much time and money had been spent on various kinds of "kidney belt," and many weeks had been spent in bed with the feet raised. For the last four weeks the attacks had been so frequent that she has had to be largely under morphia. There were many circumstances in this case which pointed strongly to gall-stones. She told us that the attacks used to come on absolutely suddenly and go off with equal abruptness. Again, they more than once followed the jolting of a motor-car drive, also there was the frequent occurrence at night in bed. It was suggested that the motions should be put through a muslin sieve for the next few days, and on the first trial a small, broken-up gall-stone was found.

Operation a few days later confirmed the diagnosis and removed the trouble permanently.

CASE 3.—A third case was seen in 1906 in a young woman (R.) aged 21 years. She was an ardent golfer and had suffered from recurrent attacks of abdominal pain for some years. For the last two and a half years these had become much worse; a swelling, thought to be the right kidney, was quite palpable below the umbilicus. The attacks were very acute, there was occasional vomiting, no jaundice, no fever. When I saw her she had just gone through a severe attack with much vomiting, during which tetany had occurred in the hands and feet on the second and third days. Food always made the pain worse. Between the attacks she was quite well. Laparotomy disclosed a large distended gall-bladder and gall-stones.

From the history it would seem that they had begun to give trouble when she was not more than 16; how much earlier they had been forming it is impossible to say.

SOURCES OF ERROR IN DIAGNOSIS.

In each of these cases the error was made of attributing the trouble to a "loose kidney," which was definitely present in two and absent in the third. Had these patients been women of 45 or thereabouts the diagnosis would probably have been made much sooner. It has been suggested that "floating kidney" with Dietl's crises may be a predisposing cause of gall-stones. My personal experience makes me suspect that many cases of "Dietl's crises" are cases of gall-stone colic from the first, in which the floating kidney is merely an accidental association.

In the next case no such difficulty as regards the kidney arose, but another factor—namely, hysteria—was allowed to interfere.

CASE 4.—The patient was a single woman of 25, of very hysterical type, with some vague history of sexual trouble earlier in life. She was admitted to the Sheffield Royal Hospital under my care in 1915, complaining of attacks of abdominal pain which had begun 15 months earlier. Hysterectomy had been performed a few weeks before the onset of this pain, but there was no definite information as to the reason for this. She was under observation in hospital for a month, and during that time had an attack which lasted several hours. In spite of the very obvious character of the pain a correct diagnosis was not made, and she was labelled "gastric neurosis." After returning home the attacks continued, and in January, 1917, I saw her again and suspected gall-stones. However, she did not feel satisfied and arranged to go into a well-known hospital in London. She was under the charge of one of the physicians there and seen in consultation by his surgical colleague, and they arrived at the conclusion that there was no evidence of gall-stones, but that the whole thing was a neurosis and operation inadvisable.

In October, 1917, I was asked to see her again whilst she was actually in an attack. There was then no doubt that she was suffering from biliary colic. In this case also the pain often came on in the night. Operation was performed and a large gall-stone was removed.

The exact notes taken by my clinical clerk on this girl's case in 1915 are as follows:—"The pain is of an aching character and starts under rib 7, right side, and gradually spreads round body in form of girdle pains, but always worst at the above region where it started: does not radiate to lower abdomen, but shoots up back to neck and head."

The description is so typical as to make the mistake in diagnosis almost incredible. It is accounted for by the fact that one is apt to forget that gall-stones do occur in young people, and secondly, that a highly neurotic person always runs the risk of organic mischief being overlooked. This is a point worth bearing in mind. The boy in the fable who called out, "Wolf! wolf!" was an undoubted hysteric. When the wolf actually did come, he suffered the fate which hysterical people often suffer in the clinical world: nobody believed him! The desire for notoriety and sympathy which filled his youthful hysterical mind has in his case been posthumously fulfilled. The next four cases are merely added to emphasise the point as to age.

CASE 5.—In 1909 I saw a typical case in a girl of 17 years. The attacks were characterised by intense pain over the gall-bladder, coming on absolutely suddenly at any time and passing off with equal suddenness in four to five hours. In the interval she was perfectly well. At operation about 20 very small stones were found. Possibly each attack represented the actual passage of a stone from the gall-bladder to the duodenum which occupied the above-mentioned time, and was too brief to cause jaundice. Probably the simple process of passing the motions through a sieve would have demonstrated the stones.

CASE 6.—In 1914 a single woman (C.), age 28, was admitted to the Royal Hospital suffering from abdominal pain. Her symptoms began when she was 15. The pain followed food at intervals varying from a quarter to one hour. An attack lasts from two to two and a half hours. She goes yellow after an attack. For the last 18 months they have been getting worse. Attacks may come on in the night. Her mother had similar attacks. The gall-bladder is palpable. At operation 351 small stones were removed from the gall-bladder. Assuming that the onset of symptoms corresponded with the first formation of stones, she had been laying down stones at the rate of about 45 per annum, or nearly one a week.

¹ See Postscript.

² Still, G. F.: Transactions of Pathological Society, London, 1899, 1, 154.

CASE 7.—A married woman (G.), aged 24, began to have attacks of biliary colic with jaundice after a confinement one year ago. At operation four small dark-brown masses were found in the gall-bladder.

CASE 8.—Married woman (V.), aged 29, had her first attack of colic five years previously. Frequent recurrence; has had many attacks in night. Operation; a large number of stones removed.

I have also gone into the question of age of onset from another point of view—namely, in connexion with the histories given by those suffering from gall-stones in later life; and it is surprising how often it is possible to get a history of vague but real abdominal discomfort dating from comparatively early adult life. The patients may tell you that the type of pain has changed, and the much more striking colic may only have begun years after the chronic so-called stomach trouble. In 30 of my cases in which the presence of gall-stones was demonstrated at operation the date of first onset of symptoms is carefully recorded as follows:—

Symptoms of gall-stones began under 20 years of age ...	4
" " between 20 and 25 " " " "	4
" " " 25 " 35 " " " "	3
" " " 35 " 40 " " " "	7
" " " above 40 " " " "	12

The number of cases may seem insignificant, but they are the only ones in which the records, on this point of date of onset, are complete and the results of operation known. As regards age of onset, these figures give numbers which, if exceptional and accidental, at any rate show that gall-stones beginning in the period of life, 15 to 30, are by no means rare in these parts.

The Dangers of Declining Operation.

It is usual at the present time to advise operation in most cases of gall-stones. Although in many cases this advice is followed, usually with the happiest results, it is not uncommon to meet with patients who cannot make up their minds to undergo the ordeal of an operation. Thus, an active vigorous man, 70 years of age, whom I saw recently, was seized with a typical severe attack of biliary colic. He had had a similar attack 15 years before, for which morphia was required, and a slighter attack, which passed off in a few hours, one year ago. He declined operation absolutely and, to a certain extent I think logically, for he said: "I have managed to carry on for 15 years without a second severe attack. Why shouldn't I go for another 15 years without one?" I have quoted this case merely as an example of what is familiar to every medical man, and I want to consider how far this patient or any other similarly affected is wise or foolish in declining operation.

What becomes of patients who know they have gall-stones and elect to keep them? They escape thereby the discomfort and the dangers inherent to every major operation. What are the discomforts and dangers to which they expose themselves?

These may be summarised under three heads: (I.) Persistence or recurrence of pain. (II.) Inflammatory complications, leading to adhesions, ulceration, gangrene, &c., necessitating an operation of urgency under conditions of considerable gravity. (III.) The occurrence of cancer in the gall-bladder region. There is also the possibility of chronic pancreatitis with its usual train of symptoms. In order to obtain some data on these points I have gone carefully through my records of cases and followed up, so far as has been possible, those patients in whom the diagnosis seemed quite clear and who declined operation. In a few of the cases stones had been passed by the bowel; in all but three jaundice had occurred, often more than once. In all the history was typical. The actual number of cases which comply with these requirements is necessarily small, as in so many there is an element of doubt. I have been able to follow up the after-histories of 26 such cases during varying periods from 20 years downwards to two years. There were 9 males, 17 females.

The first of the three questions summarised above amounts to whether a person with gall-stones is likely to have increasing frequency of attacks of colic as age advances—that is, supposing no other complications arise. So far as my limited numbers go I am inclined to answer this in the negative. On general grounds one might expect that with the increasing calm of advancing

age, and the absence of violent exercise, over-indulgence in food, and hurry, there would be less disturbance in the gall-bladder and fewer attacks.

AFTER-HISTORY OF CASES NOT OPERATED ON.

One case (Mrs. J.) had colic at the ages of 52, 58, 61, 62, and 64; she then had no further attack in her life and died of some unconnected disease at 72. So that for the last 12 years of her life she was free from attacks. A man (D. W.) had an attack when 68 and lived another 10 years without any further trouble and died suddenly. A woman (Mrs. T.) had colic attacks from the age of 61 to 64; she lived to 69, having no further attacks and dying of cerebral hemorrhage. A man (Mr. L.) had colic during his fortieth and forty-first years he is still living at 48, and has had no further attacks.

A woman (Mrs. P.) had colic and passed a stone per rectum at 45 years of age; she has had no attack since—that is, 10 years later—and is in good health.

Woman (Mrs. J.) had recurrent attacks from 38 to 56 years of age. She is now 67 and has had no attacks for 11 years.

These are not many cases on which to dogmatise, but there is another side on which we have indirect confirmatory evidence. As was said above, in a considerable percentage of autopsies gall-stones are found in persons who have died of something quite distinct. In many of these there is no history of previous illness pointing to their existence. This may mean that they have never caused any trouble at any time, but more probably it means that during the later years of life they have not done so, and since the short memory of hospital patients is well known the symptoms of earlier years have been forgotten. Although the data thus obtained is scanty, I think we may say that it is not usual for gall-stone colic per se to get progressively worse in declining years.

The second danger to which the gall-stone owner is liable is inflammatory complications and ulceration. The relative frequency of these must be comparatively small and therefore the likelihood of their occurrence in any individual case not very great. There is, of course, a risk, and when it occurs, a very serious danger. Unfortunately it is very difficult in any case of gall-stones to know, until operation, whether one is dealing with a simple uncomplicated case or with a condition of affairs which may at any moment become dangerous. The case of Mrs. X. proved to be one of this kind. There was nothing in the history to make one suspect the severe and complicated condition found by the surgeon at operation. As a matter of fact, I am informed that she had, in addition to stones in the gall-bladder, one stone loosely impacted in the common duct, the gall-bladder was adherent to the liver and to the duodenum, and ulceration had taken place between gall-bladder and duodenum.

With such a condition as this, in what seemed a straightforward case, one can never feel safe in supporting the plea of no operation, however simple the case may seem. The patient is always running the risk of urgent danger.

CARCINOMA IN PATIENTS WITH GALL-STONES.

Lastly, there is the question of carcinoma. My inquiries show that of the 26 cases followed up 13 are still living, 8 have died of malignant disease of the abdomen, and 5 from other causes. Thus of these 26, no less than 8 have already died of abdominal carcinoma. How many of these were actually primary in the gall-bladder I cannot say, as autopsies were not obtainable, but some certainly were strongly suggestive of this.

It is useless to quote percentages in dealing with small numbers like this, but it shows, at any rate, that the possibility of a terminal carcinoma in cases not operated upon is considerable and real. This is, of course, a well-known fact. Rolleston, in his "Diseases of the Liver, Gall-bladder, and Bile-ducts," goes into the question very fully, and gives interesting statistics on the subject. These vary very widely from 4 per cent. to 14 per cent.

It is worth while, however, looking into the details of my cases as to when this occurred.

1	died at 68	after having had colic for 30 years.
1	" 67	" " " "
2	" 65	" " " "
1	" 50	" " " "
1	" 63	" " " "
1	" 59	" " " "
1	" 65	" " " "

On an average these patients had suffered from colic for 17½ years before malignant disease supervened,

and their average age at death was nearly 63. Fütterer⁸ gives the average age of primary carcinoma of the gall-bladder in a large series of cases as 58 years, and Winton in a series of 60 cases agrees with this. One cannot, therefore, say that the occurrence of carcinoma of the gall-bladder is likely to be an early result of gall-stones. In fact, it might be said that in such persons carcinoma comes on at about the same period of life as in other persons, but its place of selection seems to be the gall-bladder.

CONCLUSIONS.

As I said at first, cholelithiasis is very common, and it is almost certain that the number of cases in which this condition is the cause of vague abdominal pain is even greater than is generally realised. I feel sure that in doubtful cases we neglect too much the simple method of examining the faeces by straining them through muslin after an attack of abdominal pain. It is not very troublesome, and if, as so often happens, small stones are being passed, their detection in the faeces settles the matter at once. There is every likelihood that in some few cases all the stones in the gall-bladder are eventually passed in this way and complete recovery thus occurs without operation, but this is probably a rare method of cure. A few months ago I saw an instance of this in a woman who began with severe biliary colic when 25 years of age. This recurred every month or two for ten years. The pain was so intense that the doctor was always obliged to give her a few whiffs of chloroform to relieve her until he could get his syringe ready and the morphia injected. After each attack she strained the motions through a sieve and always found a small stone. I saw her collection of these, which filled a small bottle. She declined operation. From the age of 35 up to the present time—she is now 50—she has never had another attack or any discomfort of any kind, and I suppose she has passed them all. However, this is an exceptional experience and cannot be offered as a probable result in most cases.

I think, therefore, that it is our duty to urge all those in whom the existence of gall-stones is fairly certain to undergo operation, unless there is some strong contra-indication. Although their pain may be tolerable, and perhaps only intermittent, yet it is impossible to judge how far dangerous inflammatory complications already exist, or how soon they may arise, whilst the possibility of malignant disease ending the scene is a very real one, although this may be delayed for many years.

Postscript.—Since this lecture was delivered I have seen two cases bearing upon points emphasised in it. One of these was a man of over sixty years of age, who began with abdominal pain and jaundice. He was quite certain that he had never before suffered from abdominal pain or discomfort of any kind, and in this he was confirmed by his medical attendant. This complete absence of previous pain, together with the persistence of pain and jaundice at his age, made the diagnosis of malignant disease seem probable. He was eventually operated upon, and I am informed that a stone was found impacted in the common duct and nothing else. Unfortunately he only survived the operation a few weeks. It is, of course, impossible in such a case to form the least idea as to how long the stone had been in the gall-bladder absolutely quiescent. The second case was another example of gall-stones in a young woman. She was 32 and had suffered from attacks of colic for eight years, since she was 24. The interesting point was that she had suffered from an attack of jaundice at 11 years of age. Operation showed a large number of small stones.

PORTSMOUTH WAR MEMORIAL: GIFT TO HOSPITAL.—At a meeting of the Portsmouth War Memorial Fund Committee held on Sept. 13th it was stated that the fund amounted to £21,100. It was decided to allot £10,000 to the Royal Portsmouth Hospital and to hold over the remainder for the erection of a suitable cenotaph, the cost of which was estimated at approximately the same figure. Any balance remaining is to be given to the hospital.

The Lumleian Lectures

ON THE

CLINICAL EXPERIENCES OF A PHYSICIAN DURING THE CAMPAIGN IN FRANCE! AND FLANDERS, 1914-19.

Delivered before the Royal College of Physicians of London

BY SIR JOHN ROSE BRADFORD, K.C.M.G.,
C.B., M.D., F.R.S., F.R.C.P.

LECTURE III.*

MR. PRESIDENT, FELLOWS OF THE COLLEGE, AND GENTLEMEN,—In my previous lectures I have brought to your notice some of the diseases that were met with during the campaign, and discussed some of the clinical problems presented by these; to-day I propose to deal with some of the effects produced on the chest by gunshot wounds. Chest lesions are seen not only as a result of gunshot wounds of the chest, they may also occur as a result of gunshot wounds in other and even distant parts of the body. Gunshot wounds of the chest produce many effects that are of great interest from the medical side, and in this lecture I propose to deal mainly with but one side of the question—i.e., that dealing with certain physical signs that are frequently to be observed in such cases.

LESIONS RESULTING FROM WOUNDS OF THE CHEST.

Wounds of the chest are usually classified as either penetrating or non-penetrating, and one of the most striking facts observed is that the effects produced by these very different wounds are not uncommonly very similar, and hence it may sometimes be extremely difficult to determine with accuracy whether a given wound is a penetrating or a non-penetrating one. Gunshot wounds of the chest may give rise to a great variety of lesions, such as hæmothorax, sterile or infected, pneumothorax, open or closed, sterile or infected, pneumohæmothorax, pleurisy, empyema, hæmatoma of the lung, massive collapse of the lung, rupture of the diaphragm, lesions of the pericardium, or of the heart or great vessels, &c. Further, chest wounds may be single or multiple, but I propose in this lecture to limit my remarks in the main to the consideration of the effects of unilateral wounds in the production of the condition known as massive collapse of the lung, and only to deal with other lesions in so far as is necessary in order to elucidate massive collapse.

Unilateral wounds of the chest may give rise to either unilateral or bilateral lesions. When unilateral they may be on the side of the wound—i.e., homolateral—or else on the opposite side—i.e., contralateral. When an unilateral wound causes either unilateral or bilateral lesions, these may be direct and immediate or else indirect and remote, and therefore really of the nature of complications, and then they may occur either early in the history of the case, as in certain cases of contralateral massive collapse, or else at a later period, as in the case of bronchitis or pneumonia occurring as well-recognised complications in cases of hæmothorax, &c.

Chest lesions may also be seen as a result of gunshot wounds, not of the chest, but of other and, it may be, distant parts of the body, and here also they may be either of direct or indirect origin. Thus, a wound of the face, arm, or even of the buttock may give rise to a hæmothorax by the injury inflicted by the actual track of the missile. In this case the lesion is of direct origin, and if, as is sometimes the case in wounds of the face or arm, the wound of entry is small and there is no wound of exit, the nature of the case may be overlooked at first and the chest lesion attributed not to its real cause—hæmothorax—but to some other condition—e.g., pneumonia. These cases of chest injury as a direct result of wounds in distant parts of the body are of some clinical interest owing to their diagnostic difficulties and as illustrating the often remarkable course taken by missiles in the body, but they do not present the problems that arise in cases where the distant wound leads to the development of chest lesions in an indirect manner.

* Lectures I. and II. appeared in THE LANCET, Sept. 11th (p. 535), and Sept. 18th, (p. 583), respectively.

In these cases the injury inflicted by the missile is limited to the part struck—i.e., abdomen, buttock, thigh—the chest is uninjured, and yet as a direct result of the wound a chest condition of considerable importance—i.e., massive collapse—develops.

Finally, wounds of distant parts of the body may give rise to chest lesions as a result of the development of complications, such as pneumonia, pleurisy, &c. It is evident from these considerations that the subject of chest lesions in gunshot wounds is very complex, and it is not surprising that considerable difficulty may be experienced in the correct interpretation of the physical signs in any given case.

LESIONS PRODUCED BY UNILATERAL PERFORATING WOUNDS.

Sterile Hæmothorax.

The study, firstly, of some of the lesions produced by simple penetrating wounds limited to one side of the chest, so-called through-and-through or perforating wounds, and, in the second place, the study of the massive collapse that may ensue as a result of non-penetrating wounds of the chest wall, form the subject on which I wish to address you to-day. The simplest and at the same time the most common lesion produced by a unilateral through-and-through wound of the chest is a sterile hæmothorax of varying amount.

Inasmuch as this lesion produces mechanical or physical effects somewhat similar to those seen in pleural effusion, it might on a priori grounds be assumed that the clinical picture and physical signs of these two conditions would be very similar if not identical. In both the essential abnormal condition is the presence of a variable but often large amount of fluid in the pleural cavity, and hence it might be thought that the physical signs of a sterile hæmothorax would be more or less identical with those recognised by all as characteristic of pleural effusion.

Differential Diagnosis.

A very small clinical experience of cases of hæmothorax is sufficient to show that this is not the case and that in reality the physical signs of the two conditions are very dissimilar.

In pleural effusion the classical and typical physical signs are the bulging of the affected side with impaired mobility, displacement of the heart, lack of resonance on percussion over the area of the effusion with skodaic resonance above it, diminished tactile fremitus, and weakening or absence of breath sounds with, in some cases, tubular breathing limited in its position and possibly accompanied by increased bronchophony and ægophony. If the effusion be a left-sided one diminution of resonance over Traube's space is a well-recognised and common phenomenon. Bulging of the affected side of the chest, together with weakened or absent breath sounds, and displacement of the heart are nevertheless the usual and outstanding signs of this condition. It is true that such signs may sometimes be present in cases of hæmothorax, but they are not the usual ones, and in my opinion are not the typical signs of a sterile hæmothorax. In a simple sterile hæmothorax of moderate or even of large amount the signs are rather as follows: The affected side of the chest is immobile and retracted to a greater or less degree, and notwithstanding the existence of this retraction the heart is displaced in a manner similar to that seen in pleural effusion—i.e., away from the retracted and affected side and towards the normal side. Well-marked retraction may be present when the hæmothorax is by no means small in amount—i.e., two to three pints. The retraction is not only obvious to the eye and capable of being measured by the cyrtometer, but is shown in another way—i.e., by the upward displacement of the diaphragm, which is a most constant and characteristic feature of cases of hæmothorax. This upward displacement of the diaphragm is readily detected on X ray examination, but in cases of left-sided hæmothorax it can also be determined by the increased area over which resonance can be elicited by percussion, and Traube's space instead of being diminished in area as determined by percussion is, on the contrary, greatly increased in the upward direction.

This criterion affords one of the most striking differences in the physical signs of the two conditions and in the earlier periods of the campaign was a common cause of errors of diagnosis. Further, the skodaic resonance in cases of hæmothorax is extremely well marked, and thus it may well be that in cases of quite considerable hæmothorax on the left side there may be little or no dullness on percussion over the chest anteriorly with the patient in the recumbent posture. X ray examination reveals not only the high position of the diaphragm but also shows that it is immobile. In other words, in hæmothorax the diaphragm

and the chest wall behave in a similar fashion; they both assume a position diminishing the size of the pleural cavity on the injured side and they both become immobile.

Although this retraction of the thoracic parietes in hæmothorax is in such contrast to what usually obtains in pleural effusion, yet the displacement of the heart in the two conditions is similar; that is to say, the heart is displaced towards the healthy side, and therefore away from the retracted side. Whatever the mechanism is that leads to the retraction of the chest wall and to the upward displacement of the diaphragm it is one that does not cause the heart to be displaced towards the affected side. Further, if from any cause, a moderate hæmothorax with the usual signs described above undergoes a sudden increase, as may happen when infection rapidly involves a sterile hæmothorax, the heart may undergo a further displacement, and strange to say, the retraction of the chest wall on the affected side persist. If, however, the pleural exudate becomes quite large the retraction will disappear, and then the signs will closely resemble those of pleural effusion. The retraction of the chest wall is certainly not only a most constant but also a very remarkable feature of hæmothorax, and it is strange that space should be found for the pleural contents rather by displacement of the heart than by the bulging of the chest wall. The auscultatory physical signs of hæmothorax are also somewhat different to those commonly present in pleural effusion, in that tubular and even amphoric breathing are much more frequently heard, together with greatly increased bronchophony and extremely well-marked pectoriloquy. Such signs are frequent in hæmothorax and rather infrequent, although by no means unknown, in pleural effusion.

Finally, mention must be made of the fact that the retraction of the chest wall is sometimes much more marked locally, and more especially in the lower regions of the chest posteriorly.

It is, of course, understood that the above description refers to cases of simple hæmothorax produced by through-and-through perforating gunshot wounds, and where the actual injury to the chest wall is often exceedingly slight. The retraction of the chest wall is not dependent upon any smashing injury of the chest wall, nor is it associated with any painful condition of the parietes. It may be seen in cases where the wounds are so small as almost to escape observation.

Causation of Differential Physical Signs.

When we consider the above physical signs, and more especially the retraction, the absence of bulging of the chest wall, the well-marked tubular or amphoric breathing, and the presence of pectoriloquy, together with the presence of some pyrexia and bloody sputum, it is not surprising that the presence of hæmothorax was often overlooked and the diagnosis of so-called "traumatic pneumonia" made in its stead. It was difficult to realise that the above signs were really indicative of the presence of blood in the pleura and not of pulmonary consolidation.

Post-mortem examinations showed that inflammatory complications such as pneumonia practically did not occur in lung tissue collapsed under the pleural effusion present in hæmothorax, although such complications might occur as a result of wounds where no hæmothorax was present. In other words, the presence of hæmothorax in some way prevented the development of such inflammatory complications as pneumonia or bronchitis in the collapsed lung, although such complications might occur in other portions of the lung not collapsed by the hæmothorax, either on the same or on the opposite side. The results obtained by the study of these post-mortem findings and the clinical phenomena described above led to the conclusion that the physical signs produced by a sterile hæmothorax of simple production and of moderate amount—e.g., two to three pints—were in reality totally different to those found in an ordinary acute pleural effusion of similar size, and then the question naturally arose as to the reason for this difference. The presence of such marked retraction of the chest parietes and the high level of the diaphragm suggested the question whether the collapse of the lung found post mortem was really produced by the presence of the extravasated blood and fluid exudate in the pleural cavity, or whether it had some other origin. If the extravasated blood in hæmothorax solely produced the collapse of the lung it was not obvious why the signs should be different to those of pleural effusion; if the collapse had some other mode of origin it might perchance afford some explanation. A simple explanation that presented itself was that the gunshot wound led at once to collapse of the lung on the injured side by producing a pneumothorax that was only of transitory duration, and that the blood was extravasated after the lung had already collapsed. This seemed plausible and capable of accounting for the extensive collapse of the lung often found to be present. Such a view, however, was soon shown to be

untenable, as the same phenomena were found to occur in cases of non-penetrating wounds; and further, as will be seen later, it was also negated by the occurrence of massive collapse of the contralateral type as a result of non-penetrating wounds of the chest wall.

Further clinical observation revealed, however, two types of cases that must be discussed in order to attempt to grasp the nature of the collapse of the lungs that results from gunshot wounds of the chest.

In the first type of case a unilateral penetrating wound causes the development of the following clinical picture. Physical signs are found on the injured side, such as immobility, dullness on percussion, absence of breath sounds, retraction over not only a very large area, but not uncommonly implicating the whole side, so that dullness is present up to the clavicle. In other words, the signs suggest at first that a very large effusion, filling the pleural cavity, is present, but more careful observation reveals that the displacement of the heart is either absent or else that it is somewhat misplaced towards the affected side, and that the patient, although presenting these extensive signs, is not always greatly distressed. If paracentesis be at once performed only a small quantity of fluid, it may be but a few ounces, is withdrawn. With or without paracentesis the signs clear up rapidly, sometimes in a few days, and cases have occurred where paracentesis had been ordered but postponed for some reason for 24 hours, and then when about to be done the signs had so altered that it was unnecessary. X ray examination, together with the results of paracentesis and of clinical observation, revealed that there were cases of quite small hæmothorax associated with extensive massive collapse of the lung quite out of proportion to the amount of fluid extravasated in the pleural cavity.

The results at this stage of the inquiry may be summarised by stating that it seemed that in simple penetrating wounds causing sterile hæmothorax the collapse of the lung was not directly and solely dependent upon the quantity of the extravasated blood and fluid in the injured pleural cavity. Cases were seen where the collapse involved the whole lung on the affected side and yet where paracentesis, X ray examination, and the clinical course of the case showed conclusively that a large extravasation was not present in the pleural cavity. These cases, however, present many difficulties in their interpretation, as it is obvious that a penetrating and perforating gunshot wound may give rise to many lesions of the lung that can only be surmised and not ascertained with certainty, and thus the interpretation of the massive collapse observed in such cases is open to question. For this reason we will now turn to the consideration of the second group of cases alluded to above—i.e., to the study of certain clinical phenomena the result of non-penetrating wounds of the chest.

CLINICAL PHENOMENA RESULTING FROM NON-PENETRATING WOUNDS OF THE CHEST.

Non-penetrating unilateral chest wounds may give rise to lesions of the thoracic contents either on the side injured (homolateral) or on the opposite side (contralateral). The homolateral lesions are essentially of the same character as those seen in penetrating wounds and will not be considered here as they also are often difficult of interpretation, inasmuch as it may in any given case be difficult to prove that the wound is not a penetrating one. The contralateral lesions are for our present purpose much more suitable as no such questions arise in these cases.

A non-penetrating wound of the chest wall of quite simple character, not producing any extensive local injury, may nevertheless produce a massive collapse involving the whole of the lung on the opposite and uninjured side. I wish, Mr. President, to emphasise the fact that such wounds are often very slight—i.e., certain wounds without the presence of any fracture of ribs and without the presence of any signs or symptoms pointing to damage of the thoracic contents on the side injured. Thus, such cases may not only show no physical signs of pleural or pulmonary lesions on the side injured, but they may never have suffered from hæmoptysis, a common symptom in non-penetrating chest wounds. In one of the most typical cases of massive collapse of this contralateral type that came under my observation the man walked four miles to the dressing station after being wounded, and the bullet dropped out when taking his tunic off. He had no hæmoptysis and no

serious symptoms of any kind, yet massive collapse of the whole of the opposite lung was present within 24 hours of his being wounded.

Massive Collapse of the Lung.

These cases of massive collapse of the contralateral type, produced by non-penetrating wounds of the chest, are in many respects the most suitable variety for the clinical study of the condition since some of the ætiological factors usually regarded as necessary for its production are not present in such cases.

Thus the injury is not of necessity a severe one and the patient has not been compelled to assume a constrained posture, and sometimes, as just mentioned, has not even been in bed or lying down for a long period prior to the onset of the collapse. Further, there is no injury of any kind on the side of the collapsed lung, and nothing in the history to suggest obstruction of the bronchus by blood clot or foreign body; and it is difficult to see how such an obstruction could be present as a result of slight non-penetrating wounds of the opposite side of the chest. Lastly, but by no means of little importance, no anæsthetic had been administered to such patients prior to the onset of the massive collapse. It would seem evident, therefore, that these contralateral cases arise in some manner as a direct result of the injury to the chest wall. Although this variety of massive collapse is perhaps the one with the most striking clinical picture and the one where clinically there is the least difficulty in its recognition, there are many other forms of collapse after gunshot wounds. Thus it may be seen in a homolateral form after both penetrating and non-penetrating unilateral wounds, but in both of these there may be much more difficulty both in the diagnosis and in determining with any accuracy whether obstruction of the bronchus from a foreign body is present. Thus, in non-penetrating wounds bruising of the lung and the development of a hæmatoma of the lung are not uncommon. In penetrating wounds it is very difficult to determine clinically the part played in the production of collapse by the mere presence of fluid in the pleura. Although, as described above, massive collapse quite out of proportion to any fluid present can in some cases be diagnosed with accuracy and confirmed by X ray examination and by the clinical course of the case, yet this is only done with ease in cases of very complete and extensive collapse. In the more usual type of case it might seem far fetched in any given case to suggest that the collapse was excessive in amount and out of proportion to the quantity of fluid present in the pleura. It is for such reasons that in order to demonstrate with ease and certainty the presence of massive collapse the contralateral type following non-penetrating wounds of the chest wall should be selected.

Massive collapse is seen, however, under other conditions; it may occur not only as a direct result of gunshot wounds of the chest, but also indirectly as a complication. Thus it is by no means rare as a contralateral complication in cases of unilateral hæmothorax, although in such cases it is often overlooked or else diagnosed as pneumonia. Its occurrence as a complication of unilateral hæmothorax is one explanation of those cases where there is extreme displacement of the heart, suggesting the presence of a large collection of fluid in the pleura, and where paracentesis, &c., actually shows that the amount is small. In such cases the heart is displaced not by being pushed over by the pleural collection but owing to the existence of massive collapse on the side towards which the heart is displaced. This contralateral collapse occurring as a complication of hæmothorax is very readily confounded with contralateral pneumonia, since in collapse such signs as well-marked tubular breathing, pectoriloquy, râles, &c., are, if anything, better marked than in pneumonic consolidation. The distinguishing feature between the two conditions is the displacement of the heart, but in such cases as we are now discussing it is probable that the cardiac displacement will be attributed entirely to the hæmothorax, and thus the error of diagnosis made. It is probable that in certain rare instances massive collapse may occur as a complication of hæmothorax on the same side as the hæmothorax and involve the remaining free portion of the lung. I have seen a very few instances where from the signs and symptoms it was probable that this had occurred, but the diagnosis of such a condition and the separation of it from an increasing pleural effusion is a clinical problem of some difficulty, and I do not propose to dwell on this very rare group of cases.

There is, however, another group of cases of massive collapse of considerable interest where the condition is found in association with gunshot injuries of other, and it may be distant, parts of the body. Wounds of the abdomen may be followed by the development of massive collapse, and such cases resemble those described in civil practice by our Fellow, Dr. W. Pasteur.

In such cases the aetiology may be complex, just as it is in the cases of civil practice where the collapse develops after an operation for hernia or for appendicitis, and I do not propose to discuss them here. Wounds limited to the abdominal wall, and by no means of a severe character, may also lead to the development of massive collapse, and here also it may be on the side of the chest opposite to the abdominal wall wound.

Some of the most marked instances of massive collapse that I have seen occurred as a sequel to wounds of the buttocks, and in some cases of wounds of the thigh. In all these cases the wounds were of a severe type; in the case of the thigh, fracture of the thigh was always present; and in the case of the buttock wounds, although bone injury may not have been present, wounds were always of a severe type. In all these cases where buttock or thigh wounds were present the character and position of the wounds were such as to cause great distress to the patient, and they also caused great constraint of postures. This may well have played a part in the production of the lesion. No case of massive collapse of the lung came under my observation where the wound was one affecting either the upper limb or the head.

Physical Signs of Massive Collapse of the Lung.

The physical signs present in cases of massive collapse are very definite, although they vary necessarily with the extent of lung involved in different cases, and also with the degree to which any given area of lung involved is affected; hence they not only vary in different cases but also in one and the same case at different times—i.e., at different stages in its progress. It is probable that two, if not three, stages may be recognised, and for the reasons mentioned above the signs will be described in the simplest type of case—i.e., that of massive contralateral collapse in cases of non-perforating unilateral wounds of the chest wall.

In such a case the physical signs in the first stage are retraction and immobility of the side affected, high and immobile diaphragm on the affected side, and displacement of the heart towards the affected side. The displacement of the heart is extreme; thus, if the left side be the one affected the maximum impulse may be in the mid-axilla, or, if the lesion is on the right side, the impulse may be well felt in the right nipple line. When the collapse involves either the whole lung or the upper lobe the displacement of the heart, instead of being a purely lateral one, is oblique, so that the impulse is displaced upward as well as laterally. In left-sided cases of this type the impulse may be well felt and seen in the third left space or even behind the third rib. It is remarkable that these extreme displacements of the heart are, so far as my experience goes, unaccompanied by any murmur, either basal or apical.

All cases of massive collapse present the above physical signs and only vary in the degree of their development, but the other physical signs may vary according to the period in the development of the condition at which the patient is examined. If seen early, and where the collapse involves much lung and to a considerable degree, the percussion note will be impaired or dull, the tactile fremitus deficient or absent, and the breath sounds either very weak or inaudible.

These signs, together with the retraction and cardiac displacement, are characteristic of the first stage—i.e., in cases seen early and where there is extensive and marked collapse. It is of importance to recognise that in such cases the extreme displacement of the heart is the outstanding physical sign, and were it not for this the weakening of the breath sounds and the retraction of the side might either be overlooked or not attract the attention they deserve. Such cases are often difficult of interpretation if massive collapse, as a possible cause, is not present to the mind of the observer. This first or early stage may readily be overlooked, as frequently such patients have no severe symptoms, and unless the position of the impulse is noted the existence of the collapse is not recognised.

In the second stage the physical signs are more obvious, and the bulk of cases seen come under observation at this stage, when the heart is still extremely displaced, the chest retracted, the diaphragm high, but the breath sounds, instead of being weak or absent, are tubular or amphoric in quality, and tactile fremitus is increased and pectoriloquy extraordinarily well marked. The loud character of the tubular or amphoric breathing, together with the presence of whispering pectoriloquy, causes such signs to be frequently interpreted as pneumonic in origin. In these cases the

retraction of the chest wall, although present, may not be so marked as in the first stage, and similarly the immobility of the chest may be also relative rather than absolute.

In the third stage of massive collapse the displacement of the heart is less, as the heart is returning to its normal position numerous râles and crepitations may be audible over the pulmonary area where tubular breathing, but less marked, is still audible. It is of some interest that an area of tubular breathing may persist for some days after the heart has returned to its normal position.

Such, then, are the signs of massive collapse, and the extent of their development in any given case will depend on the area of lung involved and the stage at which the patient is first seen. Massive collapse may involve the whole of one lung or the whole of one lobe or only a portion of a lobe. When it is lobar the lower lobe is the one most usually involved, but some cases of collapse limited to the upper lobe have been observed. Collapse involving the entire lung on one side has only been observed by me as a sequel of non-penetrating wounds of the chest wall, or else in association with a small hæmothorax; in the former case it was contralateral, in the latter homolateral. In other words, the contralateral massive collapse seen as a complication of hæmothorax has been either lobar in distribution or else has only involved a portion of one lobe. It is, of course, not probable that a patient could survive if suffering from a hæmothorax and massive collapse involving the entire lung on the opposite side.

Although contralateral massive collapse is not an uncommon accompaniment or complication of hæmothorax I have seen no case of massive collapse as a complication either of pleural effusion or of pneumothorax, notwithstanding the fact that a considerable number of cases of pneumothorax, the result of gunshot wounds, came under my observation. It would seem, therefore, that it does not arise as a complication of chest injuries or diseases when these are of more or less gradual origin as in pleural effusion, or, when, as in pneumothorax, their onset is marked by urgent dyspnoea.

Diagnosis.

The diagnosis of massive collapse is often difficult, more especially if the condition is not one familiar to the observer, and there can be little doubt that many cases are overlooked and regarded as of pneumonic origin.

Thus, from time to time cases are recorded in medical literature as cases of pneumonia of a peculiar character, in that the heart is displaced *towards* the pneumonic lung and where the symptoms of the patient are not such as to suggest the presence of pneumonia. When the massive collapse involves either an entire lobe or the entire lung curious errors of diagnosis are likely to be made. Thus I have known the condition mistaken for transposition of viscera in a case where after a contour wound of the left side of the chest the impulse was in the right nipple line and where the trivial symptoms present seemed to negative the possibility of collapse involving the entire right lung. Nevertheless, the progress of the case proved that this was really the nature of the case. The displacement of the impulse is sometimes attributed to cardiac dilatation, the physical signs at the left base being either overlooked or else attributed to compression of the left lower lobe by the supposed cardiac dilatation. I have known the sound normal side of the chest to have been opened under the impression that the displacement of the heart must have been due to some condition such as fluid, notwithstanding the absence of physical signs, the physical signs on the affected side being entirely overlooked or attributed to compression of the lung by the displaced heart. Further, operations have sometimes been performed on the affected side and the collapsed lung explored under the impression that the well-marked tubular breathing and râles indicated the presence of an intrapulmonary abscess. The most common error, however, is to attribute the signs present to pneumonic consolidation. This error can only be avoided by a consideration of the signs as a whole and by laying due stress on the cardiac displacement and on the absence of the symptoms of pneumonia. In most cases the diagnosis can be made with accuracy provided that it is recognised that such signs as tubular breathing are not necessarily evidence of pneumonic consolidation. In a few cases grave difficulty may be experienced because pneumonia may occur as a late complication in a collapsed lung; in such cases diagnosis would be very difficult, if not impossible, unless the patient was under observation prior to the onset of the pneumonia and when collapse alone was present. The massive collapse seen as a sequel of gunshot wounds is not,

as a rule, accompanied by urgent symptoms, and one of its most striking features is the absence of severe symptoms, notwithstanding the presence of very extensive physical signs. This may afford considerable help in diagnosis. Symptoms such as cough, dyspnoea, &c., would seem to be more marked in the post-operative variety of the affection seen in civil practice, more especially after abdominal operations, and it may be that these cases are rather of a different type.

Complications.

Complications in the massive collapse following gunshot wounds are, on the whole, rare, but certain inflammatory complications may develop in the collapsed lung, such as pneumonia, purulent bronchitis, and sometimes pleural effusion.

In cases under observation it can be clearly ascertained that these are true complications in that they supervene on an initial condition of pure collapse, but if only seen after the complication has developed it is probable that their true nature would not be recognised. When a pleural effusion develops as a complication in a case of massive collapse very remarkable physical signs are produced in that the pleural effusion may cause a displacement of the heart, so that it tends to return to its normal position, the retraction of the chest still persisting. With the increase in the size of the pleural effusion the retraction of the chest wall diminishes and may disappear, and then the signs become similar to those of an ordinary pleural effusion. It is, however, of interest that for a time in such cases retraction of the chest may be present; room is found for the fluid not by bulging of the chest wall but by displacement of the heart. The occurrence of bronchitis as a complication of massive collapse is also of interest, as it is in marked contrast to the absence of bronchitis in lung collapsed beneath a hæmothorax, a point I have already alluded to in the earlier part of this lecture. I am under the impression that those inflammatory complications in massive collapse are more liable to occur in the cases of post-operative origin, and in those complicating severe gunshot wounds of the buttocks and thighs. I have not seen them in the cases of massive collapse following the slighter non-penetrating wounds of the chest wall, although the massive collapse present in these cases may be of the most extensive variety and involve the whole of one lung. In cases where death has occurred as a result of pneumonia involving a collapsed lung, it is of interest that on post-mortem examination the lung, although solid, is not of the large size usual in pneumonia. This is especially obvious where both the collapse and the subsequent pneumonia have been limited to one lobe.

Nature of Massive Collapse.

There are many difficulties in the way of any simple explanation of this remarkable condition, and more especially of the variety described above as contralateral collapse, the sequel of non-penetrating wounds of the chest. Collapse of the lung is so readily produced by anything obstructing the bronchial passages that it seems natural to invoke some such mechanism in these cases.

Where massive collapse in one or other of its forms occurs as a sequel to a penetrating wound it must necessarily be difficult to exclude the possibility of the presence of blood or other foreign body in the bronchi in any given case. In the case of non-penetrating contour wounds with no symptoms of any urgent character it would seem very unlikely that any such cause is operative, more especially in the contralateral cases. The practical question would seem to be whether the immobility of the thoracic parietes in these cases is the cause, and the pulmonary collapse the result, or whether the chest wall is immobile because the lung is collapsed primarily. In the absence of any evidence pointing to the presence of a foreign body in the bronchial passages, the only other mechanism would seem to be obstruction of the bronchioles by muscular contraction or pathological exudation. It is difficult to accept either of these possibilities to explain massive collapse involving an entire lung in the absence of any symptoms pointing to bronchial obstruction. Lesions of the smaller bronchi causing obstruction to the entry of air produce symptoms and signs of considerable urgency; in these cases these phenomena are absent. In cases where a patient is confined to bed or has to assume some constrained posture, the hampering of the full respiratory movements of the chest may lead to the retention of secretions in the bronchial passages, and so increase or perhaps produce some varieties of collapse; but such an explanation will not meet the cases of massive contralateral collapse. Impairment of the movements of the chest wall and of the diaphragm are, however, most important factors in causing collapse of the lung directly, as has been noted by previous observers, especially J. Pearson Irvine, and W. Pasteur. If the respiratory movements ceased on one

side of the chest the lung on that side might collapse, if not by the "deflation" postulated by Pasteur, at least as a result of the absorption of the air in the lung by the circulating blood. There is perhaps no great difficulty in attributing massive collapse to loss of respiratory movement of the thoracic wall and diaphragm, and some of the facts I have brought to your notice would seem to suggest that the chest wall is not merely passive. Thus, in hæmothorax, where retraction of the chest wall may be well marked, the heart is displaced, as in pleural effusion, away from the affected side. It is difficult to understand how this comes about if the condition of retraction is not an active one. Further, in cases of massive collapse, when pleural effusion occurs as a complication, the heart undergoes the usual displacement. The difficulty is not that immobility of the thoracic parietes is not an adequate mechanism for the production of collapse, but rather that it is so difficult to understand how this condition should supervene on one side of the chest as the result of a more or less trivial injury to the opposite side. The condition of the chest wall presents some analogy to that of the abdominal wall in cases of injury or disease of the viscera, but it is doubtful whether it is more than an analogy and it would seem as if more experimental work is required before an adequate explanation of the phenomena of massive collapse can be given.

The study of these cases of massive collapse of the lung as the result of gunshot wounds suggests that collapse of the lung is a very common, perhaps the most common, result of a gunshot wound of the chest, although in a very large proportion of cases its presence is masked by the development of a hæmothorax. I am of opinion that this is the reason why the physical signs of a simple sterile hæmothorax are so often different from those of a pleural effusion. In the latter the collapse of the lung is produced gradually in association with the pleural exudate; in the former massive collapse of greater or less extent is produced more or less suddenly, and the hæmorrhagic effusion of the hæmothorax is only in part responsible for the collapse of the lung present.

ON THE

END-RESULTS OF PERIPHERAL NERVE INJURIES TREATED BY OPERATION.

(Being the substance of an introductory address to the Section of Surgery at the Annual Meeting of the British Medical Association.)

By WILLIAM THORBURN, K.B.E., C.B., C.M.G., F.R.C.S.,

PROFESSOR OF CLINICAL SURGERY, MANCHESTER UNIVERSITY;
SENIOR SURGEON TO THE ROYAL INFIRMARY, MANCHESTER;
TEMP. COLONEL, A.M.S.

In civil life injuries to the peripheral nerves, although by no means rare, do not occur in sufficient numbers to allow of the collective investigation which they receive in war. Hence much of our earlier clinical knowledge was founded upon the work of Weir Mitchell during the American Civil War, and since that time research has been conducted mainly either on experimental or pathological lines or on the limited clinical opportunities of a few observers. The European war has again supplied us with a large amount of material, which has been thoroughly studied, and which has been treated under the most modern surgical conditions.

Great numbers of these cases have been submitted to the operation of secondary suture, and not a few to that of grafting, so that we may hope that it will be possible ultimately to express almost in a statistical form the end-results which have thus been obtained. This day, however, has not yet arrived, and a long period of time and a careful series of observations by neurologists and anatomists will be required for full investigation. We are thus not yet able to give a perfect picture of end-results; all that can be done is to collate some of the more complete records and to formulate what may perhaps be regarded as an interim report.

The Legitimate Limit of Hope.

It may now be agreed that the regeneration of a peripheral nerve is in all cases accomplished by the downgrowth of axons from the proximal end into

channels or sheaths awaiting them at the peripheral end. The proximal axon is connected with a sensory or motor neurone, while the peripheral sheath leads to, or is connected with, a terminal organ, either motor or sensory.

Apart altogether from anatomical continuity, it must be recognised that repair which may lead to a good functional result requires that a sufficient number of axons shall enter into a sufficient number of peripheral sheaths which are capable of leading them in the right direction. Thus, for example, motor axons entering channels connected with sensory terminals are probably lost for ever, and so with afferent axons which become connected with muscle-endings. So far as I know, the union of a purely motor with a purely sensory nerve is not followed by any physiological connexion whatever.

Clearly, motor axons must enter motor channels and afferent axons sensory channels. Not only is this the case, but it is important that as far as possible the down-growing axons should enter the identical channels for which they were originally intended. Thus, if the spinal motor cells for, let us say, the extensor longus pollicis become connected with the peripheral channels for the brachialis anticus, which lie in the same nerve, physiological confusion will result, and the spinal cord will not be able to produce the movements which the brain demands.

Similarly, irregular connexion of afferent nerves with terminal organs in the skin or elsewhere for which they were not intended will necessarily lead to more or less of chaos in the interpretation of afferent impulses. No doubt errors of this type can be to some extent corrected by means of education, but such re-education will be necessary in the great majority of cases of nerve suture, and it is especially necessary in connexion with suture after the excision of large cicatrices from complicated junctions such as the brachial plexus.

Macroscopic and Histological Shunting.

We are thus brought face to face with the question of shunting, or, as the French call it, "aiguillage," of axons into peripheral channels. Shunting may be gross or macroscopic, as when the proximal end of the hypoglossal or spinal accessory nerve is attached to the distal end of the facial, in which case a limited physiological result may be obtained. Motor axons here enter channels for which they were not intended, and the resulting movements are confused and imperfect, but they can and do occur.

The gross shunting of a purely sensory on to a purely motor nerve or vice versa can produce no result at all. The operation which has been adopted in the past of implanting the two ends of a cut nerve into an intact adjacent nerve ignores altogether the essential linking up of original channels, and has in practice entirely failed. In this connexion I would urge that the word anastomosis, which is founded on a false analogy between nerves and hollow channels such as blood-vessels, should be entirely abandoned. Anastomosis in the real sense of the term never occurs, and the use of the word is apt to lead to confusion of thought.

Apart, however, from gross or macroscopic shunting, histological shunting probably occurs in the vast majority of operations. In the case of end-to-end suture every endeavour is made to avoid errors in shunting by preventing rotation of the approximated ends; but even with this precaution some error probably always occurs, owing to the nerve fibres running in a spiral course, so that, however perfect the anatomical adjustment, the minute apposition is not likely completely to restore the axons to their original channels. To a much greater extent this difficulty arises when a graft has been interpolated. In such cases the axons of the proximal end are expected to enter the neutral channels of the graft, to pass through them, and then, so far as possible, to re-enter their proper channels at the other end of the graft. It is clear that under such conditions the prospects of correct shunting will be at least very greatly diminished, and that, even if good anatomical results can be obtained, the physiological results are likely to be most imperfect.

Economic Value of the End-result.

We have one other consideration of importance in judging of an end-result. Such a result can be anatomically good in the sense that nerve continuity is restored; it may be physiologically or neurologically satisfactory to the extent that on stimulating the nerve every muscle with which it is connected may be made to contract and the whole of its cutaneous distribution may present at least some sensation, but we have also to consider what I may call the economic value of the end-result.

A result which is neurologically good may be economically poor, in the sense that the patient is unable to use the affected part as he ought to do. Such defect may be due to psychical conditions, to the secondary changes of muscular atrophy or of arthritis, or possibly to a form of ataxia in which, while all muscles are capable of action, they can only be properly used while their action is under visual control. This local ataxia, which may render economically imperfect an otherwise excellent limb, is probably due to want of restoration of the deep afferent fibres by which are judged and controlled perfect muscular action.

Alternatively, and more fortunately, the economic result may be better than the physiological result. Thus in cases of injury to the ulnar nerve with well-defined symptoms, those who do not require the finer movements of the hand may find little practical inconvenience, and even a complete lesion of this nerve may exist without recognition by the patient. Again, vicarious movements may admirably replace those of lost muscles. How varied such vicarious movements may be and to what a degree patients may conceal paralysis which actually exists is well illustrated in a recent paper by M. F. Forrester-Brown.¹ Vicarious movements and substituted movements of this type have an enormous economic value, but they constitute a veritable pitfall in the estimation of neurological results for those who are not constantly upon their guard or not thoroughly familiar with the possibilities of misreading end-results. The importance of their consideration is illustrated by the fact that I have personal knowledge of cases reported by good observers as "cured" in which there is no neurological evidence whatever of regeneration; and it is never possible to rely upon the statements of patients as evidence that recovery has occurred after operation.

A Summary of Reported Results.

Turning to some of the more extensive series of reported results, they may be thus summarised:—

Of 108 personal cases of suture or grafting analysed by Tinel,² 14 were complete failures, 22, or say 20 per cent., showed practically complete recovery, and the remainder were regarded as improved.

S. W. Daw³ says that 40 per cent. of his cases showed signs of returning motor power after seven months.

J. Sherren⁴ found that of 21 cases of secondary suture some return of motor power took place in all, but that it was never complete.

R. Kennedy,⁵ examining after a long period cases occurring in civil life, claims that 73 per cent. of all sutures were completely successful.

Dumas⁶ investigated 115 personal cases of operation for war wounds of one nerve only, the musculo-spiral; but it must not be forgotten that for several reasons this yields better results than any other nerve. He claims evidence of recovery in 42 per cent. of his cases, and of some regeneration in 65·2 per cent., the remaining 35 per cent. being presumably entire failures.

J. L. Joyce⁷ found in 36 cases of secondary suture 8 recoveries, 6 with considerable improvement, 8 with some improvement, and no result in 14.

H. S. Souttar and Twining⁸ found that of 61 cases of

suture 7 recovered, 32 were recovering at the time of report, 7 were doubtful, 2 were failures, and 13 were not traced; but their results, like those of Joyce, would probably be improved by a later report, as in many cases the time elapsed had not been sufficiently long.

Adson⁹ reports the results of operation on 41 cases, four-fifths of which were end-to-end suture and the remainder plastic operations. Of 30 cases traced "the average amount of improvement obtained was 58 per cent. return of the sensory, 62 per cent. return of the motor, and 67 per cent. return of the trophic function"; 73.1 per cent. showed improvement.

These figures, which are by no means easy to compare, leave the impression that secondary nerve suture gives very good results in somewhere between one-third and two-thirds of all cases, but the most careful study of original articles, as well as my personal experience, leads me to believe that a perfect neurological recovery is rarely if ever obtained. Permanent disability may be masked in various ways, but is almost invariably to be detected if carefully searched for. Complete failures are by no means uncommon, and must be looked for in a very definite percentage of even the best operations. Such appear to be the general results in the case of secondary suture.

Grafting as a Last Resort.

In the case of grafting, as we have already seen, much less is to be hoped for. Certain isolated cases are reported in which brilliant results are claimed, and it is, of course, possible that the anatomico-pathological difficulties to which I have referred may occasionally be overcome, but there is certainly as yet no large number of good results obtained from grafting. Personally I have no experience at all of this operation, and it will, I think, be found that the greater the experience of end-to-end suture the less often the need for grafting will be found to arise. So much can be done by bold operating, by extensive exposures, by thorough stretching of nerve trunks, by alteration of their anatomical course into a shorter bed, and by the operation of stretching in two stages that grafting will always be, and should always be, a last resort. I have yet to see personally any cases in which it has been a success. I have seen cases in which it has been reported as successful, but which to my mind did not carry conviction. I hope, however, that there are those present who will be able to establish a claim to have obtained results more fortunate than I have met with.

A number of facts now well established materially influence our prognosis in the case of different nerves and different levels of these nerves. Nerves which supply large muscles, and especially muscles of homogeneous type, such as the musculo-spiral, give much better results than those whose muscular distribution is small and complicated, such as the median and ulnar. Nerves also which are mainly motor or mainly sensory are more amenable to treatment than those whose function is more complicated. In both these cases, no doubt, the ill-effects of bad shunting bear more heavily upon the more complicated trunks. Dual lesions are more serious than single ones, so that a combined injury of the median and ulnar nerves is susceptible of very little improvement indeed.

Factors in Recovery: Time.

The time required for recovery is very great. On the basis of what is known as Tinel's sign the downgrowth of axons occurs at the rate of about 1 mm. per diem, which would require, say, 200 days for a fibre to grow from the wrist to the tip of the index finger, or two years from the middle of the thigh to the foot. The slow return of epicritic sensation, even after a perfect primary suture, is admirably indicated by Sherren's operation upon Head. An ophthalmic surgeon under my care some years ago divided the digital branches of his left middle and ring fingers near the web by a cut from a piece of glass, and did not obtain perfect tactile sense for 18 months or two years.

On the other hand, the rate of recovery is not in such direct proportion to the length of nerve to be traversed

as was formerly believed, and probably a large share of the time actually occupied is required for the linking up of axons with end-organs and for re-education. In this connexion J. S. B. Stopford¹⁰ has some most interesting figures; analysing 58 cases of suture of the musculo-spiral nerve in the lower, middle, and upper thirds of the arm he finds that the supinator longus begins to recover after about four, five, and seven months respectively, other muscles showing similar differences; so that it takes only about three months longer for recovery in a section close to the axilla than in the case of a section quite near to the origin of the branch for the supinator longus.

It would also appear from the work of Professor Stopford, who has most carefully tested 271 cases of nerve suture, that recovery is more perfect the nearer the suture is to the spinal cord, which may be due to its closer connexion with its trophic centre or to the greater ease of surgical operation upon thicker trunks.

Before concluding I should like to refer to the so far unpublished results obtained at the Grange Hospital Military Hospital in Manchester, staffed by old students of my own, with whose work I am thoroughly familiar. Most of the operating work here has been performed by H. Platt, and the results have been checked by Professor Stopford from a purely anatomical and neurological point of view. In a recent communication to the Royal Society of Medicine Professor Stopford states that in no cases of secondary suture can the result be described as perfect. At the best there has been a perceptible difference in power when comparing the two sides, and at least an incomplete recovery of epicritic sensibility, even three and a half years after the date of the suture. The recovery of sensation has been particularly disappointing.

Local Peculiarities.

Of sutures in the upper arm, failures amounted to 12 per cent., and in the forearm to 24 per cent. At both levels the recovery of voluntary power has been much less over muscles supplied by the nerve in the distal than in the proximal part of the limb. On the whole, it may be concluded that a good functional result is to be expected after secondary suture of the musculo-spiral nerve. The extensors of the wrist usually regain full power, the extensor communis digitorum recovers satisfactorily, but the extensors of the index finger and thumb are much less perfect.

As regards the median nerve, in quite a large proportion only incomplete recovery of protopathic sensibility has occurred, and voluntary power in the abductor brevis pollicis has only been found in 45 per cent. The ulnar nerve is particularly disappointing, and the recovery of voluntary power in the small intrinsic muscles of the hand was exceedingly poor. On the other hand, from the economic point of view, it is interesting to note that many of these injuries to the median and ulnar nerves did not prevent the patients from obtaining employment. I do not propose to weary you with details in reference to the nerves of the lower limbs.

These remarks apply to cases which date back for a period of three years; still further lapse of time may improve them, but will also tend to confuse the issue by permitting of improved vicarious function. As they stand they are, I believe, a perfectly fair expression of the best efforts of the surgery of to-day.

As to the dates at which recovery, if any, can be expected after the operation of nerve-grafting we have no reliable statistics, and the comparatively few records of such recovery which will even bear investigation are not numerous enough for generalisation.

Treatment of Nerve Compression.

In the treatment of compression of nerves my own experience has been very considerable, and almost, if not quite, uniformly successful. I have in the past had many examples of operation for compression of nerves, and I do not think that, however grave the symptoms, I have ever failed to obtain recovery which was at least economically complete; I have not the details to

⁹ Adson: *Annals of Surgery*, August, 1919, p. 169.

¹⁰ J. S. B. Stopford: *Brain*, vol. xliii., Part I., 1920.

show how far they were neurologically perfect. My personal experience thus differs sharply from that of Kennedy, who found that neurolysis yielded slightly less good results than nerve section and suture. I have only one reservation to make: after the removal of pressure by cervical ribs it is most rare for atrophy of muscles to be entirely repaired: this I am inclined to attribute to the fact that a chronic neuritis has followed the original pressure lesion, and that such neuritis leaves indelible changes which are rarely found in traumatic cases of pure compression.

I have not painted the picture in rosy colours; the greatest optimism is generally that of the man who records a few remarkable cases—often a single case. After many years I can only say that if a surgeon obtains 50 per cent. of really good economic recoveries after secondary nerve suture he is doing well; if he obtains 75 per cent. of such recoveries, which will bear investigation, his work is both brilliant and fortunate.

PROGNOSIS IN CERTAIN AFFECTIONS OF THE HEART.¹

By W. T. RITCHIE, O.B.E., M.D., F.R.C.P.E.,

PHYSICIAN TO THE DEACONESS HOSPITAL, AND ASSISTANT PHYSICIAN TO THE ROYAL INFIRMARY, EDINBURGH.

To those who are suffering from affections of the heart prognosis is of the utmost importance. The parents of the boy whose heart was strained ask whether he may safely indulge in any form of athletics at school; others wish to know whether the condition of the heart will debar their son from entering one of the Services. The young man wonders whether the valvular heart disease for which he was invalided from the army is any bar to his intended marriage, or a life assurance company may desire to know his expectation of life. The anxious wife's first question is will her husband be spared, and he himself soon begins to inquire whether he can look forward to complete recovery, or whether he must needs relinquish all, or only some of, his former activities. To the physician prognosis is also an important problem because the treatment he recommends is often based not only upon a correct interpretation of the patient's symptoms and physical signs, but also upon a reasonably accurate forecast of the degree of health to which the patient may be restored.

It may be said that prognosis in heart disease is notoriously speculative and uncertain, and it is true that many intercurrent factors may arise and upset our most careful estimate of the patient's future. Nevertheless, there are certain general principles which we recognise as of the utmost value in guiding us to the knowledge that whereas one patient will make a complete recovery and another may look forward to some years of relatively good, though impaired, health, the life of another is fast drawing to a close.

Prognosis is primarily always dependent on accuracy of diagnosis. The precise data furnished by radiograms, the sphygmomanometer, the polygraph, and the electrocardiograph have placed diagnosis on a firm basis, and the co-relation of this knowledge with symptoms and physical signs has now become so well-established that in practice we can usually dispense with the electrocardiograph and other elaborate instrumental methods.

Cardiac Affections.

The prognosis in relation to cardiac affections is practically always more favourable if organic disease of the heart can be excluded. I do not hold with the theory which sought to minimise or to deny the unfavourable effect of organic valvular disease. Now, no one seriously believes that men with organic valvular disease are really first-class lives, or even that they are fit for military service in category A. It is true that some men with organic valvular disease are fit for a hard game of football, or for strenuous physical work, but these cases are exceptional. In the course of the

acute endocarditis from which the patient suffered some years previously there were probably more focal inflammatory lesions in the myocardium than we suspected, and these must have left some permanent damage to the heart muscle. Consequently a chronic valvular lesion, apart from the mechanical disability it imposes upon the heart, thereby lowering its reserve force, is often associated with at least some degree of chronic myocarditis.

The prognosis, however, should never be founded solely on a study of the heart. We have to take into consideration the patient's age, sex, and occupation, the state of the arterial walls, the blood pressure, the efficiency of the kidneys, and the state of the pulmonary and other systems. Moreover, we have to remember that chronic degenerative changes due to spirochaetal infection are slowly progressive, this being of particular importance in relation to aortic incompetence; whereas acute rheumatic lesions of the myocardium and endocardium are liable to recur, especially if the primary source of infection, whether it be in the tonsils or elsewhere, cannot be located and removed. Even after all the available data have been elicited and weighed we are reminded of the fact that no two cases are exactly comparable, and that each individual case must be judged on its merits.

I do not propose to enter upon the consideration of the phenomena associated with the patient's response to physical exertion, though this is of the greatest value in determining the functional state of the heart muscle, and consequently in ascertaining, for example, whether there is some degree of cardiac failure in addition to valvular disease. Nor shall I consider the symptoms and signs which collectively indicate pronounced cardiac failure, nor the prognostic significance of deficient renal activity in heart disease; but I shall limit my remarks to certain of the more common cardiac disorders which we encounter in the course of our daily work.

Dilatation of the Heart.

Let us first consider the prognosis in dilatation of the heart. I shall not deal with the dilatation which follows as a late and often terminal result of myocarditis, with or without valvular disease, but wish to speak of the cardiac dilatation which apparently ensues as a direct result of some unusual physical stress, or which is first recognised during, or in the early phase of convalescence from, an acute infective illness.

In regard to the former group of cases—namely, those usually spoken of as cardiac overstrain—it may safely be affirmed that physical exertion never causes a pathological degree of dilatation in a perfectly healthy heart. The recognition of this fact renders it difficult, or impossible, to give a wholly favourable prognosis to a patient suffering from cardiac overstrain, although the immediate prognosis may be good. The patient has usually attained an age which makes it almost certain that arterio-sclerosis has already begun, and we remember that age is a matter of tissue change, not merely of years.

The case of a joiner, aged 52, affords a good illustration. He was employed in a colliery, and enjoyed excellent health until he volunteered for the unaccustomed work of firing boilers during a miners' strike. Ten months later he was still breathless and fit for little work; the heart was preserving its normal rhythm, there was no dropsy, and no murmurs were audible, but the blood-pressure readings were high, the diastolic pressure being 85 and the systolic pressure 170, and after slight exertion the pulse-rate took four minutes to decline to its pre-exertion rate of 90. In such cases of cardiac overstrain the patient must be content to live on a lower plane of activity than formerly. He must avoid calling upon the heart, the reserve force of which is lowered, for more work than it can successfully undertake, and any physical effort which occasions dyspnoea, pain, or præcordial distress is harmful. The best advice to give to most of these patients is that which I learned from Cowan, of Glasgow—namely, that an active or a merry life will mean a short one.

In cases of cardiac dilatation from acute infective disease the chief difficulty centres in the question of

¹ A paper read before the Medico-Chirurgical Society of Edinburgh on July 7th, 1920.

diagnosis. The patient has passed through an acute febrile illness, often of rheumatic or influenzal nature, the heart has become slightly enlarged, the pulse-rate remains somewhat too frequent, and a systolic murmur has become audible. Has one of the valves been damaged by endocarditis or is the heart merely dilated? It is principally when the systolic murmur is maximal at the cardiac apex that we have to consider the possibility of its being an indication of recent endocarditis which, even although the immediate prognosis be favourable, will leave the mitral valve permanently damaged and will probably cause grave incapacity in the course of years. My own experience has taught me that an apical systolic murmur is almost certainly due, not to organic mitral incompetence, but to dilatation if the apex-beat is not displaced and not unduly forcible, if the murmur is soft in quality and confined to the apical region, if the intensity of the murmur varies notably with change of posture, and if the pulse retains its physiological respiratory irregularity. The conclusion thus arrived at is strengthened if the patient is anæmic, and if there is a functional systolic murmur at the pulmonary, and possibly also at the tricuspid, area.

In these cases of cardiac dilatation the prospect of complete recovery is good. The murmur may persist for weeks or months, but ultimately disappears entirely. It is now a frequent experience to find the heart perfectly normal in men who one, two, or three years ago were invalided out of the army because they presented a mitral systolic murmur which had led to a diagnosis of V.D.H. We are now observing on a vast scale the phenomena to which George Balfour drew attention in his classic observations on "curable mitral disease."

Disorderly Action of the Heart.

Passing to another common disorder, D.A.H., we recognise this as a symptom-complex, protean in origin, and by no means confined to those who have served in the army. When the man who was always a weakling, unfit to play games at school, and who found his true level in a quiet, sedentary, unambitious walk of life attempts to undertake larger responsibilities, he becomes incapacitated by the giddiness, fatigue, palpitation, præcordial pain, and other symptoms characterising this disorder. We all recognise that this type of person will never become robust. Those in whom the disorder has arisen as a sequel to shell concussion, or in civil life to some other form of trauma, may be expected to improve slowly if under judicious treatment.

After excluding these cases, and those in whom we find visceroptosis, obesity, arterio-sclerosis, early pulmonary tuberculosis, hyperthyroidism, and so forth, we find that in over 40 per cent. of all patients who are said to suffer from D.A.H. there is evidence of some recent infection, and in an additional 10 per cent. there is anæmia, presumably of toxic origin. In all these cases—50 per cent. of the total—the prognosis is, in my opinion, good. The disturbance may be essentially one of the endocrine glands or of the autonomic nervous system, but it is not the heart that is primarily at fault. If we give a guarded prognosis, keep the patient confined to bed, permit the attention of devoted relations, administer digitalis (which is of no value to the patient), and exercise an anxious watchful supervision lest the patient overtax the heart, we confirm the patient in the belief that he is suffering from serious heart disease, and the condition progresses from bad to worse.

A good prognosis is the first essential in restoring the patient's confidence. He must be told he is not suffering from heart disease, that the heart is healthy, and that he will make a complete recovery. He should not be allowed to lie in bed; the less he is waited on and the more he does for himself the better, for the more he accomplishes the greater the degree of self-confidence he regains. During the first few days massage and passive exercises are of value. When he first begins to walk about his tolerance of exercise is naturally poor, but he should be encouraged to undertake an increasing amount of physical exercise daily. Within a few days he should be performing active physical exercises under skilled supervision; he is then encouraged to

take active exercise out of doors. Drugs are seldom indicated; digitalis is wholly useless.

This method of treatment seldom fails, and is usually speedily and eminently successful in restoring the patient to health. It was so in the army. Of nearly 2000 men under my supervision, 69 per cent. became fit for full duty in the front line; and in 1918, when our organisation for physical testing and training had reached its maximum efficiency, no less than 86.9 per cent. of Class A men, admitted to hospital for D.A.H., became fit to rejoin their units. Relapses very seldom occurred.

In civil life the prospects of full recovery are not so uniformly good. The patient does not lead such a healthy life as does a soldier in a command dépôt; he is now less amenable to control. Physical training, needing skilled supervision, is costly and not so efficient as it was in the army; there are devoted relatives whose influence is the reverse of helpful; and in certain grades of the community there is the sure expectation that incapacity for work will be compensated by grants from public funds. Nevertheless, brilliant results may be obtained, even under the adverse conditions of civil life, and a man or woman who has been practically bedridden for months may, within a few weeks, be leading an active and useful life. The cases in whom the dominant manifestations are those of neurasthenia are the most intractable and the most prone to relapse.

Extrasystoles.

Passing to the most common of all forms of cardiac irregularity—namely, extrasystoles. The prognosis should never be based on the extrasystoles alone, but rather on the underlying cause. If they are due to sympathetic stimulation of the heart under the influence of the emotions, or to obvious toxæmia from tobacco, and if the patients are otherwise healthy a favourable prognosis may unhesitatingly be given. Extrasystoles are likewise not of serious significance if they arise, even without definite cause, in young adults in whom the heart is healthy and in whom there are no signs of cardiac failure. That the immediate prognosis in these cases is good is demonstrated by the fact that of 34 soldiers sent to the base solely on account of extrasystoles 22 were proved to be fit for category A after a short stay in hospital and in a training centre. In civil life the conditions are equally favourable for recovery. I cannot recall a single instance of extrasystoles, arising in a young man or woman whose heart was otherwise normal, being the precursors of more grave heart affections. In illustration I refer to one patient who, at the age of 48, was suffering from syphilis of the lung, the arteries were healthy, and the heart, save for extrasystoles, was normal. Seven years later he was in rude health. In another, aged 41, extrasystoles were observed during a mild rheumatic attack. He made a complete recovery and enjoyed good health for nine years, when the strain of carrying on his business during the war led to insomnia and other nervous symptoms, and in the course of examination a slight mitral leak was detected.

In patients over 40 years of age, however, extrasystoles arising without obvious cause should be regarded with some suspicion, for they probably indicate commencing sclerosis of the coronary arteries. The extrasystoles are the first danger signals, and the man's expectation of life is not first class, although it may be several years before any further manifestations of arterio-sclerosis can be elicited. In these cases the determination of the blood pressure is of particular value, for we know that arterio-sclerosis is often the direct sequel to high blood pressure. In cases with any symptoms of cardiac failure a most careful examination of the pulse should be made in order to ascertain whether there is any alternation of the pulse after the extrasystoles. Even transient alternation, with alternate weak and strong beats, is always of evil omen, and I am in accord with those who find that these patients seldom survive for more than one, or at most two, years. In the aged extrasystoles are not only frequent, but are usually attended with remarkably few symptoms and with a relatively good prognosis.

Extrasystoles arising in the ventricles are, on the whole, attended with a better prognosis than those arising in the supra-ventricular portions of the heart—namely, auricular and nodal extrasystoles. Whereas a man with ventricular extrasystoles and thickened arteries may continue at his work for some years before becoming seriously incapacitated, the heart of an individual with auricular or nodal extrasystoles has been failing before they were observed.

The isolated, or single, extrasystole is of lesser significance than multiple extrasystoles occurring in series and causing momentary attacks of palpitation or of tremor cordis, because multiple extrasystoles are not infrequently the forerunners of paroxysmal nodal tachycardia, of flutter, or of fibrillation.

Auricular Fibrillation.

Lastly, as to the prognosis of auricular fibrillation. When this begins we know that the last act has begun. How long will it be before the curtain finally falls? It may be within a few weeks or it may be ten or more years. The prognosis is generally more favourable in those with mitral disease than in those with arteriosclerosis and myocardial degeneration. Apart from this there are four great factors which influence the prognosis: (1) Those without much acceleration of the ventricular rate suffer least and survive longest, whereas a high ventricular rate is unfavourable. (2) The response of the heart to digitalis. Those in whom the ventricular rate is readily controlled by this drug or by strophanthus may for years lead quiet lives with little discomfort. (3) Those in whom the ventricles do not become dilated remain comparatively well, whereas in those who develop dropsy the prognosis is much more grave. The first attack of dropsy is seldom fatal, but it recurs from time to time, and on each occasion recovery becomes more tedious. (4) Finally, we may observe symptoms and signs of chronic nephritis; the cardiac patient has become a cardio-renal one, and we know the fatal issue is within measurable distance.

EFFECTS OF HOT AND COLD APPLICATIONS ON THE SUPERFICIAL AND DEEP TEMPERATURES.

BY J. J. R. MACLEOD, M.B., CH.B., D.P.H., F.R.S.C.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF TORONTO;

A. R. SELF, M.A.,

RESEARCH ASSISTANT TO THE RESEARCH COMMITTEE OF THE
DEPARTMENT OF MILITIA AND DEFENCE OF CANADA;
AND

N. B. TAYLOR, M.B., CH.B.,
CAPTAIN, C.A.M.C.

(From the Laboratory of Physiology, University of
Toronto.)

THAT the local application of heat or cold to the surface of the body is of value in the treatment of a variety of clinical conditions is well known, but no data apparently exist to show the extent to which the application causes actual change in the temperature of the underlying tissues. With the aid of the Research Committee of the Medical Services of the Department of Militia and Defence of Canada we have undertaken to carry out a series of observations to collect such data, and the interesting and definite character of the results has prompted us to offer a brief account of them at the present time.

The Apparatus.

The observations have been conducted on rabbits. Heat or cold was applied over an area of shaved or closely clipped skin by means of an appliance which we have styled the "applicator." For heat two types of these have been used—either an electric pad (9.5 cm.), giving with 0.6 amps., temperatures ranging up to 55°C., or a water applicator, consisting of a glass tube of 20 mm. internal diameter, closed at one end by a thin rubber membrane and having water from a heat-insulated reservoir circulating through it at a definite and constant temperature.

The exact temperatures at the point of contact of the applicators with the skin was recorded from time to time during the observations by means of thermo-electric couples placed either in the cloth covering the electric pad or just inside the rubber membrane of the water applicator. To measure the temperatures of the tissues thermo-electric couples mounted within hypodermic needles were used. The couples were made of copper constantin wires, the ends being twisted together, and the junction coated with shellac. The sharp ends of the hypodermic needles were sealed with a little solder, so that the couple, occupying about 4 mm. of the needle, lay as near as possible to its point.

The position of the thermo junction in the tissues was determined by measurement of the depth to which the needle was inserted into the tissues, and the angle which it made with the surface. The couples were connected with an Ayrton-Mather dead beat galvanometer, and with a Leeds and Nothrup precision potentiometer, giving direct readings down to 1μV. Since the above couples have a thermo-electric force of 40μV. per degree C., this means that differences of $\frac{1}{40}^{\circ}$ C. could be measured with precision. The couples were calibrated by placing the hot junctions (in the hypodermic needles) in a bath of warm water with a stirrer and noting the temperature differences corresponding to given E.M.F.'s. The cold junction was placed close to the bulb of a sensitive certified mercury thermometer in water near room temperature in a large Dewar flask. From the results a calibration curve was constructed. The above method has been adopted after trial of several others, and we are greatly indebted to Professor E. F. Burton, of the Physics Department of Toronto University, for his valuable assistance in this part of the work.

Observations of Normal Temperatures.

A series of preliminary observations of the normal temperatures in the muscles and rectum were made, both before and during the application of local heat at a point of the body far removed from the thermo couple; Table I. gives the results.

TABLE I.

Temp. in muscle.		Temp. in rectum.		Duration of observation.	
Initial.	Heating opposite leg.	Initial.	Heating leg.	Before heating.	During heating.
°C.	°C.	°C.	°C.	Min.	Min.

39'7-39'8	39'7-39'2	—	—	28	50
37'2-36'0	—	38'0-38'0	—	57	—
37'7-36'9	36'9-37'0	37'6-36'7	36'7-36'4	50	32
38'4-38'4	38'4-38'2	38'7-39'0	39'0-38'8	20	25

Note.—These figures being taken from curves the second decimal is omitted.

The initial temperatures, it will be seen, varied in the rectum between 36.7° and 39°C. with an average of 37.92°C., and those in muscles between 36.9° and 39.7°, with an average of 37.90°C. Usually, the rectal temperature was a fraction of a degree above that in muscle, and the average deep temperature was somewhat above the normal usually given for rabbits. This difference is of no significance in the present investigation, the important point being that the deep temperature, as measured in the rectum or in muscle, did not change much over considerable periods of time and was not affected by the local application of heat to the surface of the body at some distance from the thermo couple, even when the temperature in the applicator was 15°C. above that of the skin.

The normal temperature under the skin varied according to whether the fur was clipped closely with the scissors or was completely shaved off. Without removal of the fur, in 13 observations on different days the skin temperatures varied between 36.9° and 39°C., the average being 37.94°C. or practically the

same as in the muscles; after removal of the fur by shaving the readings in nine different observations varied more widely (from 31.38° to 35.85°C.), with an average of 34.2°C. These results are important, since they illustrate the heat-conserving influence of the fur, the variability in the readings after shaving being, no doubt, dependent upon the cooling influence of the air. Observations on this relationship, in which the katha-thermometer of Leonard Hill is used, will be reported in a later communication. Meanwhile, it is interesting to note that the above observations were made during the winter months, when, although the room was artificially heated, its mean temperature was decidedly lower than during June. In five other observations made during this month the (shaved) skin temperatures, with one exception, were all over 34.4°C.

In all of the experiments in which the skin was shaved a second thermo couple was placed in the muscles immediately under, and at varying depths from, the one in the skin. The differences observed between the skin and muscle temperatures in degrees centigrade in 14 experiments were as follows: $3.27, 3.4, 1.2, 0.87, 2.16, 4.97, 2.93, 2.10, 0.12, 2.3, 1.9, 1.0, 3.2$, and 2.4 . The variability is mainly due to differences in skin temperature, that of the muscles being very much more constant. The figures indicate the extent to which the superficial blood loses heat by radiation and convection from the uncovered skin. General anaesthesia was not found to have any appreciable effect on these values.

Influence of Local Heat.

Coming now to the influence of local heat, the following types of observation have so far been made.

1. Temperature of skin of thigh on application of electric pad. The first observations were made with the fur unshaved, the initial temperature, as already pointed out, being, therefore, not appreciably different in the skin and in the muscles. Table II. gives, in condensed form, the most significant results.

TABLE II.

Temp. of pad.	Difference between temp. of pad and skin.	Temp. reached in skin.	Extent of rise in temp.	Temp. of pad.	Difference between temp. of pad and skin.	Temp. reached in skin.	Extent of rise in temp.
$^{\circ}\text{C.}$	$^{\circ}\text{C.}$	$^{\circ}\text{C.}$	$^{\circ}\text{C.}$	$^{\circ}\text{C.}$	$^{\circ}\text{C.}$	$^{\circ}\text{C.}$	$^{\circ}\text{C.}$
43.5	6.3	42.1	4.9	50.2	11.9	43.2	4.9
44.8	6.9	42.7	4.8	50.65	13.55	44.6	7.5
46.65	8.65	42.45	4.45	50.8	13.2	42.8	5.2
47.5	10.6	42.1	5.2	55.05	17.85	45.15	7.95
48.55	9.35	43.2	4.5				

Up to a temperature difference of 12°C. the skin temperature, it will be seen, rose about 5°C. , a moderately warm applicator having almost as great an effect as one that was considerably warmer. In later observations, in which the skin was thoroughly shaved, a similar relationship between the rise of skin temperature and the temperature of the applicator was not so evident. This is probably to be accounted for by the fact that in these cases the skin temperatures, as already pointed out, were considerably lower and much more variable than in the cases where the fur still remained on the skin.

The extent of lateral spread of the temperature change (on shaved skin) was found to be considerable. Thus, in four observations with the (water) applicator well insulated so that no heat could radiate on to the skin beyond its edge, no change was observed at 35 mm. distance, but was quite definite at 19, 16, and 10 mm., the applicators being at temperatures from 11° to 15°C. above that of the skin.

2. Temperature of skin and underlying muscle of thigh on application of hot-water applicator, to overlying skin.

Although the observations (see Table III. and Fig. 1) are insufficient to indicate the maximal depth to which locally applied heat may penetrate the tissues they show at least that this is considerable (over 20 mm.). The rise in the muscles is more gradual than under the skin. The heat of a poultice or of fomentations must therefore penetrate for a considerable distance, even into relatively vascular tissues.

TABLE III.

Temp. of pad.	Difference between temp. of applicator and muscles.	Temp. reached in muscles.	Rise in temp.	Depth of thermo couple.
$^{\circ}\text{C.}$	$^{\circ}\text{C.}$	$^{\circ}\text{C.}$	$^{\circ}\text{C.}$	mm.
43.41	6.91	38.29	1.79	20
45.83	7.31	38.42	2.07	12
46.70	9.00	39.70	2.00	18
46.14	9.20	39.21	2.27	17
46.87	11.79	39.15	4.07	17
49.48	14.55	37.95	3.02	9
48.61	10.39	40.10	1.88	16
46.50	10.53	39.8	3.83	16
48.42	11.32	38.64	1.54	17

FIG. 1.—Curves showing temperatures (in $^{\circ}\text{C.}$) on ordinates at the times indicated on the abscissa, immediately under the (shaved) skin over the gluteal region and in the muscles at a depth of 12 mm. Both the thermo couples, by which the temperatures were recorded, were under the centre of the hot-water applicator. A., applicator. M., muscle. S., skin. The two vertical lines mark the time during which the heat was applied.

3. Temperature in various regions of the abdomen on application of heat to the abdominal wall. Needles were introduced in various regions of the abdomen and the electric pad applied unheated to the surface, and the current then gradually turned on. Even though the temperature of the pad, covering approximately one-half of the abdomen, was raised slowly to 55°C. , there was no change in rectal temperature. On

FIG. 2.—Curves showing temperatures (in $^{\circ}\text{C.}$) on ordinates at the times indicated on the abscissa, just within the abdominal wall and in the small intestine 30 cm. from the jejunal junction at a depth of 54 mm. from the hot-water applicator which was applied to the surface of the abdomen. A., applicator. B., intestine. W., just inside abdominal wall. The two thick vertical lines mark the time during which the heat was applied.

the other hand, the heat spread rapidly through the abdominal wall itself; thus, when the couple was placed just inside the wall and under the applicator a rise of 4°C. was observed with the temperature difference of 13.13°C. When the couple was 17 mm. distant from the edge of the applicator the rise was 0.32°C. , and when it was 35 mm. distant no change in temperature occurred.

Between the abdominal wall and the rectum the temperature spread was found to be considerable, the observation being made on (anaesthetised) animals which were killed afterwards, and the exact position of the couple ascertained by dissection. It was found, with a temperature difference of 12° to 16° C. in the applicator (covering the upper left quadrant of the abdomen), that the temperature within the caecum rose through from 3° to 5·16° C.; just behind the caecum it rose 1·12° C. and in the wall of the ascending colon 4·04° C. The curves of one of the experiments of this series are given in Fig. 2, one needle (B) being just within the abdominal wall and the other (A) in the small bowel 30 cm. from the jejunal junction and 7·5 cm. from the point of application of the heat, at a depth of 5·4 cm. below the surface. The rise in this needle, though small (0·3° C.) is yet perfectly definite, and that it was an effect of the applied heat is indicated by the immediate fall following the removal of the applicator. The results in general show that when heat which is about 15° C. above that of the body is applied over approximately one-fourth of the surface of the abdomen a change in temperature may occur which may penetrate the abdominal viscera for a distance of about 75 mm., although it can only spread laterally for somewhat less than 20 mm.

Finally, we have completed a sufficient number of observations on the effects of cold to be in a position to state that the results are equally as definite as those for heat, the temperature change being, of course, in the opposite direction.

THE COMPLEMENT-FIXATION TEST IN PULMONARY TUBERCULOSIS:

ITS USE AS A MEANS OF DIAGNOSIS.

By A. L. PUNCH, M.B. LOND., M.R.C.P. LOND.,

ASSISTANT PHYSICIAN TO THE BROMPTON HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST.

(A Preliminary Report to the Medical Research Council.)

SINCE Bordet and Gengou¹ in 1903 demonstrated the presence of antibodies capable of uniting with tubercle bacilli and fixing complement in the sera of tuberculous animals, numerous attempts have been made to make use of this fact to obtain a reliable biological test for tuberculosis in human beings. A study of the literature of the subject indicates that although there has been considerable diversity in the results obtained by different observers, yet on the whole there has been a steady improvement in the technique employed and in the reliability of the results obtained.

This diversity in the results appears to be largely attributable to differences in the technique employed by various observers and more especially in the character of the antigen employed.

Previous Observations.

Wassermann and Bruck² in 1906 treated tuberculous patients with tuberculin and showed that the blood serum of such patients contained antibodies capable of fixing complement in the presence of tuberculin. Citron³ subsequently showed that the blood serum of tuberculous patients who had not been treated with tuberculin exhibited the same property of fixing complement in the presence of tuberculin. Various other observers, such as Wolff and Muhsam,⁴ Cohn,⁵ Koch,⁶ and others, elaborated the technique of Wassermann and Bruck, and by using tuberculin as an antigen obtained positive results in definitely tuberculous patients in from 33 to 78 per cent. of cases. Besredka⁷ in 1914 found that by using a special tuberculin he obtained a large percentage of positive results in definitely tuberculous patients. Kuss,⁸ Inman,⁹ and others proved, however, that this antigen was not specific, in that a considerable number of non-tuberculous syphilitic subjects gave a positive reaction with it.

The most recent workers in this field have used an emulsion of tubercle bacilli as antigen; these included Frugoni,¹⁰ Caulfield,¹¹ Dudgeon,¹² and, most recently of

all, McIntosh and Fildes.¹³ Here, again, the results have been variable. The last-named observers investigated a series of cases of tuberculosis of various organs. As the present investigation deals exclusively with pulmonary tuberculosis their figures will be considered in relation to this form of tuberculosis only. They obtained out of 43 cases of definite phthisis, as evidenced by the presence of tubercle bacilli in the sputum, 33 positive results, or 76 per cent. In 18 cases of "clinically certain" tuberculosis of the lung or pleura, not verified bacteriologically, they obtained ten positive results, or 55·5 per cent. As the diagnosis of a "clinically certain" case of phthisis is so largely dependent upon the individual clinician's criterion of what is "clinically certain," no definite conclusion can be drawn from these latter figures without some knowledge of what such criteria were.

Other workers using an emulsion of tubercle bacilli as antigen have obtained variable results, with the percentage of positive results in definite cases of phthisis, in some cases higher, and in some lower.

Object of the Investigation.

This investigation deals only with the application of the test to cases of pulmonary tuberculosis, and it was undertaken with a view to seeing if it were possible by modifications of the test to obtain results of sufficient reliability to warrant its being regarded as a specific reaction for the diagnosis of active tuberculosis.

The Difficulty Encountered by Previous Workers: Methods which have been Attempted to Overcome It.

In order that a reaction may be regarded as a specific test for the presence of active pulmonary tuberculosis it is necessary that a positive result should be obtained in 100 per cent. of cases definitely suffering from phthisis, or at all events in at least 98 per cent. of cases, for 2 per cent. is surely within the permissible limits of error, and at the same time no positive results should be obtained in cases definitely not suffering from tuberculosis.

The bulk of the workers on the subject are, I think, agreed that a positive result is only given in the presence of a tuberculous lesion. The difficulty hitherto encountered has been that of obtaining a sufficiently high percentage of positive results in cases known to be suffering from tuberculosis to warrant the conclusion that those cases that gave a negative result were not suffering from this disease.

The difficulty of obtaining positive results in definitely tuberculous cases has caused a doubt to be entertained as to whether the antibodies are present sufficiently constantly to make them of value for diagnostic purposes. It is certainly true that the complement fixing powers of the blood of tuberculous subjects is often infinitely less than that of syphilitic subjects, so that unless we can increase the amount of anti-substances a much more sensitive test is necessary to demonstrate their presence.

At the outset an attempt was made to increase the antibodies by administering minute doses of tuberculin (B.E.) to the patients in the hope, upon purely theoretical grounds, that tuberculous subjects would turn out more antibodies into the blood than non-tuberculous ones. As this procedure did not appear to have any effect upon the results it was abandoned. It was found, however, that the maximum amount of antibodies were present in a serum which had been allowed to remain in contact with the clot, after withdrawal of the blood from the patient for a period of 24 hours. This is in accordance with observations of Nesfield,¹⁴ and bears out the suggestion of Metchnikoff, Danys, and Kauthack, that antibodies are formed by the leucocytes. In some of the early cases in the investigation the serum was pipetted off as soon as the blood had clotted, with a result that a negative reaction was obtained in several cases definitely suffering from phthisis, but on repeating the test, observing the precaution of keeping the serum in contact with the clot for 24 hours, a positive result was obtained.

Since it did not appear evident how the antibodies could be increased the course adopted was to make the test progressively more and more sensitive and so endeavour to detect the smallest quantities present.

The Danger of Making the Test Too Sensitive.

The danger to be encountered in making the test too sensitive is of obtaining non-specific summation effects. The blood serum of non-tuberculous individuals is capable, though in my experience to a very small extent, of causing a certain degree of fixation of complement in the presence of tubercle bacilli and so, if the test is made very sensitive, of giving non-specific effects. If all non-tuberculous sera possessed this property in an equal degree it would be a simple matter to estimate once and for all the amount of complement so fixed and add it to the minimum hæmolytic dose of complement used in the experiment. But this is not so. Some sera do not possess it at all and others to a varying extent.

The problem was to determine the maximum amount of fixation that could be due to non-specific effects and then to employ a technique whereby any fixation over and above this could be clearly demonstrated.

The Maximum Amount of Non-specific Fixation.

The results of my experiments have very definitely convinced me that this property of the blood from non-tuberculous subjects is never sufficient to fix as much as half the minimum hæmolytic dose of complement as determined in the antigen titration. Usually it is much less than this, and often absent altogether.

Method Employed of Making the Test More Sensitive.

At the outset of the investigation $2\frac{1}{2}$ times the minimum hæmolytic dose (M.H.D.) of complement as determined in the antigen control was used in the experiment. When using this amount of complement 66 per cent. only of cases known to be suffering from pulmonary tuberculosis gave a positive result.

It seemed possible that although antibodies were present in the blood they were there in insufficient quantities to fix $2\frac{1}{2}$ times the M.H.D., and so be demonstrated when using this amount of complement. So that a second series of tubes were put up, using $1\frac{1}{2}$ times the M.H.D. in addition to those containing $2\frac{1}{2}$ times the M.H.D. By this procedure the positive results in cases definitely suffering from pulmonary tuberculosis was increased to about 90 per cent. A third series of tubes was then put up in each case, using once the M.H.D. It has already been mentioned that some sera from non-tuberculous individuals are capable of causing non-specific fixation in the presence of tubercle bacilli, and that these experiments tend to show that if we take half the M.H.D. as the maximum amount of complement that such non-specific sera can fix we are well over the possible limit that this property can reach. If, then, exactly the minimum hæmolytic dose of complement were used in the experiment anything more than 50 per cent. inhibition of hæmolysis would indicate some specific fixation and a positive result. But it is impossible in one tube only to determine the degree of inhibition of hæmolysis. All we can accurately determine is complete inhibition or complete hæmolysis. But if in addition to the tube containing exactly the M.H.D. of complement the other tube containing one and a half times the M.H.D. be employed in each experiment, then in the latter tube fixation can go on to the extent of 50 per cent. of the M.H.D. before there is any evidence of inhibition of hæmolysis in that tube, so that the smallest deposit of undissolved corpuscles would indicate some specific fixation and a positive result.

It might be argued that if any particular serum under examination had no power of non-specific fixation, and at the same time the specific antibodies present were less than sufficient to fix half the M.H.D., a negative result would be given in a definite case of phthisis. But the results of the experiments tend to the conclusion that in all cases of active phthisis specific antibodies are present in the blood in sufficient quantity to cause of themselves fixation of at least half the M.H.D. of complement, and as a rule of very much more than this.

The Reagents used in the Test.

1. *The antigen.*—The antigen used is an emulsion of live tubercle bacilli. A growth is obtained upon a glycerine potato medium prepared as follows:—

Slices of potato are cut as for the preparation of an ordinary potato medium, and put to soak for $1\frac{1}{2}$ hours in a 6 per cent. solution of glycerine in water to which sufficient of a 1 per cent. solution of gentian violet has been added, so that the resultant solution shall contain gentian violet in the proportion of 1 in 6000. The potato is then removed from the solution and placed in potato tubes, the bulbs of which

are filled with 6 per cent. glycerine. The tubes are then autoclaved at 115°C . for 15 to 20 minutes.

A culture of tubercle bacilli can be obtained upon this medium directly from a tuberculous sputum after treatment with antiformin in the usual way and subcultures taken from this. After the inoculated tubes have remained in the incubator for 24 hours to ensure of no contamination having taken place, the cotton wool closing the mouths is impregnated with paraffin.

Upon this medium more than sufficient growth is obtained in one tube in from 10-14 days to make up 100 c.cm. of antigen.

The advantages of this medium are that a rapid growth of tubercle bacillus is obtained, that the yellow colour of the growth is clearly differentiated from the brilliant violet colour of the medium, and that the slice of potato can easily be removed from the tube, is easily handled, and the growth can readily be scraped off the firm medium without the removal of any of the latter.

To make up the antigen for use, a sufficient quantity to make an emulsion of 1 in 2000 is then scraped off into a Hayden's mortar. This is thoroughly emulsified dry, three drops of fresh normal saline are then added, and after further emulsification three more drops, and finally 14 drops of saline added. The resultant emulsion is then sucked up into a pipette and placed in a flask. Sufficient normal saline to make the required dilution of 1 in 2000 is then added gradually, the mixture being thoroughly agitated after each addition. The antigen is then ready for use. This antigen must be made up freshly on the day of each experiment. The keeping powers of such an antigen seem to be very doubtful, and if a fresh emulsion is not used very discordant results are obtained.

The amount of antigen employed in the experiment has been kept constant at 0.5 c.cm.

2. *The patient's serum.*—5 c.cm. of blood are withdrawn from a vein in the arm and placed in a sterile test-tube. The test-tube is then allowed to stand at the room temperature for 24 hours, after which the serum is pipetted off the clot. The serum is then inactivated for one hour in a water-bath at 55°C .

Quantity of serum used in the experiment: Quantities of serum varying from one to eight drops were tried and the most constant and satisfactory results were obtained by employing four drops, so that this amount has been adhered to in all experiments.

3. *Hæmolytic amboceptor.*—This has in all cases been an antiserum.

4. *Blood.*—The blood in all cases has been a 5 per cent. suspension of washed sheep's blood.

5. *Complement.*—The complement is obtained from a single guinea-pig on each occasion.

Technique of the Test.

The technique employed is identical in principle with that laid down by McIntosh and Fildes for the performance of the Wassermann reaction. But at the risk of repeating much that is common knowledge, the stages of the test will be described in some detail in order to bring out clearly certain not unimportant points.

1. *Titration of the Complement.*

A dilution of 1 in 24 of guinea-pigs' serum is made. Five Wassermann tubes are taken and the diluted serum and normal saline added in the following amounts:—

	Tubes (1)	(2)	(3)	(4)	(5)
Complement (c.cm.)	0.05	0.1	0.15	0.2	0.25
NaCl (c.cm.)	0.95	0.9	0.85	0.8	0.75

These are then placed in a water bath at 37°C . and 0.5 c.cm. of sensitised sheep's corpuscles added. At the end of half an hour the tubes are removed from the water-bath and the readings taken. In a majority of instances complete hæmolysis will have taken place in the third tube and either no hæmolysis or incomplete hæmolysis in the first and second tubes.

A complement of sufficiently high potency that 0.15 c.cm. of 1 in 24 dilution of serum will cause complete hæmolysis or one of greater potency than this is satisfactory for the performance of the test. But a less potent complement than this—one, for instance, with which complete hæmolysis occurs only in the fourth or fifth tubes—does not give satisfactory results. It is especially in the last two tubes in the test, in which exactly the minimum hæmolytic dose of complement is used, that unreliable results are given if a complement of low potency is used. If, then, in titrating the complement there is no hæmolysis or only incomplete hæmolysis in the third tube the complement should be discarded and a fresh guinea-pig bled.

The necessity of using a serum whose complementing power is potent has very little practical disadvantage, as most guinea-pigs will supply a serum sufficiently potent in

its complementing power that 0.15 c.cm. of a dilution of 1 in 24 will cause complete hæmolysis of 0.5 c.cm. of sensitised corpuscles, especially if particular care be taken not to employ a pregnant animal.

2. The Titration of Complement in Presence of Antigen.

The next stage consists in the titration of the complement in the presence of a fixed amount of antigen to determine the minimum amount of complement which will cause complete hæmolysis in the presence of antigen. The antigen as prepared in the manner described above has a definitely anti-complementary action; hence more complement is required to hæmolyse the corpuscles in the presence of the antigen than in its absence. The extent of this anti-complementary action of the antigen appears to be in direct proportion to its strength.

Five tubes are again taken and complement, normal saline, and antigen added in the following proportions:—

	Tubes (1)	(2)	(3)	(4)	(5)
Complement (c.cm.)	0.05	0.1	0.15	0.2	0.25
NaCl (c.cm.)	0.45	0.4	0.35	0.3	0.25
Antigen (drops)	10	10	10	10	10

The tubes are placed in a water-bath at 37° C. for one hour, and then the sensitised corpuscles added. They are allowed to remain in the water-bath for half an hour. In my experience, with an antigen of the strength above described, there will be incomplete or no hæmolysis in the last tube in which there was complete hæmolysis in the titration in the absence of antigen, but there will be complete hæmolysis in the tube next to it to the right.

That is to say, an antigen of this strength is anticomplementary to the extent of 0.05 c.cm. of complement. This titration should, however, be carried out in each experiment. The same strain of tubercle bacilli has been used in all the experiments. Whether or no different strains would be anticomplementary to a varying degree I do not know. In this way the minimum hæmolytic dose is arrived at.

In using the term minimum hæmolytic dose one is only speaking relatively when working with differences of 0.05 c.cm. of complement. That is to say, if there were complete hæmolysis in the fourth tube and incomplete hæmolysis in the third the actual minimum hæmolytic dose lies somewhere between 0.2 and 0.15 c.cm. of complement. This suggested that it might be advisable to get nearer to the true M.H.D. by working with finer differences of complement. So that a series of experiments were done, using differences of 0.025 c.cm. of complement between each tube. Experience proved, however, that, although by this means one could get nearer to the true M.H.D.—0.175 c.cm., say, instead of 0.2 c.cm.—differences of 0.05 c.cm. were sufficiently fine for practical purposes.

3. The Test.

For each serum to be examined six Wassermann tubes are taken. The antigen, patient's serum, complement, and saline are added as follows:—

	Tubes (1)	(2)	(3)	(4)	(5)	(6)
Patient's serum (drops)	4	4	4	4	4	4
Normal saline (drops)	10	10	10	10	10	10
Antigen (drops)	10	10	10	10	10	10
Complement (c.cm.)	0.5*	0.5*	0.5†	0.5†	0.5†	0.5†

* Containing 2½ M.H.D.

† Containing 1 M.H.D.

Tubes 1, 3, and 5 are, of course, the controls. All tubes are well shaken and placed at the room temperature for three-quarters of an hour. They are then transferred to a water-bath at 37° C. for three-quarters of an hour. At the end of this time the sensitised sheep's blood is added. The tubes are then left in the water-bath for a further half-hour and then removed and the readings taken.

Reading the Results.

Bearing in mind what has already been said with regard to the maximum amount allowed for non-specific fixation, the reading of the results will be quite simple.

Occasionally, for some reason I am unable to explain, it may require a little longer than half an hour for complete hæmolysis to take place in the controls containing the highest dilution of complement. But an extra five minutes or so in the water-bath will effect complete hæmolysis, and this does not in any way vitiate against the reliability of the results, for as much as an hour or an hour and a half will not bring about hæmolysis in any tube in which there is true specific fixation. In a very strongly positive result there will be no hæmolysis at all in tubes 2, 4, and 6.

In a less strongly positive result complete hæmolysis may have taken place in tube 2, but little or none in tube 4, and none in tube 6.

In the least strongly positive of all there will be complete hæmolysis in tube 2, and there may be very considerable hæmolysis in tube 4, but, and this is the most important point of all, the hæmolysis in this tube will not be complete, there will always be some turbidity of the fluid, indicating

that more than half the M.H.D. of complement has been fixed; in the sixth tube there is usually no hæmolysis, and always less than 50 per cent.

In a negative result there will usually be complete hæmolysis in all the tubes, but in a certain number of cases the hæmolysis in tube 6 will not be complete, but the hæmolysis in tube 4 is always complete. The tubes are then placed in an ice chest over night and the readings verified in the morning.

In a positive result there will always be some undissolved corpuscles collected at the bottom of tube 4.

In the tables below the following plan of recording the results has been adopted.

If there appeared to be complete or over 50 per cent. of inhibition of hæmolysis in the second tube, with complete inhibition in tubes 4 and 6, the result is recorded as +++. If there appeared to be no inhibition of hæmolysis or under 50 per cent. in tube 2, but over 50 per cent. in tube 4, the result is recorded as -++. A result recorded as --+ signifies that there was less than 50 per cent., but always some inhibition of hæmolysis in tube 4.

Up to the present it has not been possible to discover any obvious correlation between the strength of the reaction given and either the extent of the disease, its duration, or its probable clinical course. Some early cases and some advanced cases have given a strong reaction, other early cases and other advanced cases have both given a positive reaction in the highest dilution only, and cases apparently doing well have given both strong and weak reactions in different instances, as have cases apparently progressing rapidly.

It follows from this that the first two tubes in which 2½ M.H.D. is used could be omitted from the experiment. But they have been and are still being retained partly for the sake of comparison of the later with the earlier results and partly in the hope that careful study of the subsequent history of each case may reveal some prognostic or other significance in the strength of the reaction that does not at first sight seem evident.

Results.

The investigation extended over four stages. Stage 1 was purely experimental, and no results were recorded. In stage 2, 2½ M.H.D. only of complement was used. In this stage 66 per cent. of cases having tubercle bacilli in the sputum gave a positive result. In stage 3, 2½ M.H.D. and 1½ M.H.D. were used, and 90 per cent. of cases having tubercle bacilli in the sputum gave a positive result. A detailed consideration of these results would be of no value, as the percentage of positive results in cases known to be suffering from pulmonary tuberculosis was not sufficiently high to warrant any conclusion being drawn from the negative results.

In stage 4, 2½, 1½, and 1 M.H.D. were employed in each case, and the results thereby obtained will now be considered in detail.

Classification of Results.

For the purpose of classification the results have been placed in four groups.

Group 1, in which tubercle bacilli had been found in the sputum at the time of performance of the test.

Group 2, in which tubercle bacilli were found in the sputum subsequent to the performance of the test.

Group 3, other cases giving a positive result.

Group 4, cases giving a negative result.

Stage 4.—In which three dilutions of complement were used—namely, 2½ M.H.D., 1½ M.H.D., and 1 M.H.D. as determined by the antigen control.

Group 1.—In which T.B. were present in the sputum at time of test (Table I.).

Group 2.—In which T.B. have been found in sputum subsequent to performance of complement-fixation test (Table II.).

Group 3.—Other cases in which T.B. had not been found in the sputum up to the time of writing this report in which a positive reaction was obtained in one or more dilutions of complement (Table III.).

It must be appreciated that in a considerable number of the cases in this group the test has been performed within the last month or so, and there can be no doubt that in many of them T.B. will be found in the sputum at a subsequent date. All the cases in Table II. were at one stage in this table, and the former table is rapidly increasing at the expense of the latter. The sputa of

the cases in this group are, of course, being examined when present at regular intervals for the presence of T.B. In some cases the disease may have become arrested, as is probable in No. 38.

TABLE I.

No.	M.H.D.			No.	M.H.D.			No.	M.H.D.			No.	M.H.D.		
	2½	1½	1		2½	1½	1		2½	1½	1		2½	1½	1
1*	-	+	+	14	+	+	+	27	0	+	+	39	-	+	+
2*	-	-	+	15	-	+	+	28	+	+	+	40	-	+	+
3*	-	-	+	16	+	+	+	29	-	+	+	41	+	+	+
4*	-	+	+	17	+	+	+	30	-	+	+	42	+	+	+
5*	0	+	+	18	-	+	+	31	+	+	+	43	+	+	+
6*	-	-	+	19	-	+	+	32	+	+	+	44	+	+	+
7*	-	+	+	20	+	+	+	33	+	+	+	45	+	+	+

9	-	+	+	22	+	+	+	35	+	+	+	47	+	+	+
10	-	-	+	23	+	+	+	36	+	+	+	48	+	+	+
11	-	+	+	24	+	+	+	37	-	+	+	49	+	+	+
12	0	+	+	25	+	+	+	38	+	+	+	50	-	+	+
13†	-	-	-	26	-	+	+								

* These cases were done previously in lower dilutions of complement and with negative results.

† 0 signifies that there was insufficient blood sent for all dilutions. All cases, therefore, in which T.B. were present in the sputum at the time of examination of the blood gave a positive result save one (No. 13).

‡ Case 13.—This was a case which was diagnosed a bronchiectasis, and which had all the typical symptoms and physical signs of this condition. But on the third routine examination of the sputum T.B. were said to be present. The sputum has been examined frequently since, but the presence of T.B. has not been confirmed. So that it is reasonable to assume an error on the third routine examination.

TABLE II.

No.	M.H.D.			No.	M.H.D.			No.	M.H.D.			No.	M.H.D.		
	2½	1½	1		2½	1½	1		2½	1½	1		2½	1½	1

4	+	+	+	10	+	+	+	16	+	+	+				
5	-	-	+	11	+	+	+	17	+	+	+				
6	-	+	+	12	0	+	+	18	-	+	+				

* Group 4.—Other cases giving a negative result in all three dilutions. Of these there were 92. Examining these cases in detail their condition is shown in Table IV.

Summary of Results in Stage 4.

Group 1.—If we exclude Case 13, on the grounds that the finding of tubercle bacilli in the sputum was an error, 100 per cent. of the cases having T.B. in the sputum at the time of performance of the test gave a positive result.

Group 2.—100 per cent. of cases in which T.B. were found in the sputum subsequent to the performance of the test had given a positive result.

Group 3.—There appears to be a reasonable conformity between the positive results in this group and the clinical condition of the patients. In a majority of the cases there were present either symptoms or physical signs or both, strongly pointing to the presence of an active tuberculous lesion in the lung or pleura. In many such symptoms and physical signs were sufficiently marked to constitute a clinically certain case of tuberculosis. This group will, of necessity, be continually decreasing at the expense of Group 2. For in many of the cases included in Table III. the test was performed quite recently when the sputum had only been examined once or in some cases before the sputum had been examined at all.

Group 4.—There appears, also, a reasonable conformity between the negative results in this group and the clinical condition of the patients. Many were definitely suffering from diseases other than tuberculosis, some were healthy individuals, and in none were the physical signs and symptoms present which would constitute a clinically certain case of phthisis, save, perhaps, in Case 82, Table IV., in which a positive Wassermann reaction was present and the possibility of syphilis of the lung has to be considered.

Special Points Suggested by the Results.

1. Persistence of antibodies in the blood after arrest of the disease.—In Cases 26 and 38 (Table III.) a positive

result was obtained. In neither of these cases were T.B. present in the sputum, nor were there any definite physical signs or symptoms pointing to active disease, but in both T.B. had been found in the sputum at a previous date. In Case 38 records were obtainable which proved beyond a shadow of doubt that the patient

44	Blood sent for Wass., which was neg.	91	Child of 11. Cough "always." Pneumonia 5 times. No a.p.s. now.
45	No cough, expectoration, or hæmoptysis. Crepitations at rt. base.	92	No cough or sputum. ? hæmoptysis Jan., 1920.
46	No a.p.s.	93	Diag. "fibrosis of lt. lung, ? cause." Girl of 18.
47	Sputum streaked with blood previously. No a.p.s. No sputum now.		

was in 1916 and 1917 suffering from active pulmonary tuberculosis. On clinical grounds it would appear at present to be a case of arrested pulmonary tuberculosis. In the other case the evidence was not quite so conclusive, but it was definitely stated that T.B. were present in the sputum on one occasion at least.

The persistence of antibodies in the blood after the arrest of the disease is in conformity with what we know of immunity in other pathological states, and it will be a point of interest to follow up such cases to determine the duration of such persistence of antibodies in tuberculosis. This consideration does not in any way affect the reliability of the test as a means of diagnosis of active tuberculosis if it be borne in mind that a positive result indicates the presence of a tuberculous lesion which is active at the present time or has been so within a recent date.

2. *The significance of a positive reaction.*—The above results do not support the view that the presence and intensity of the reaction is in any way dependent upon the actual size of the lesion, for a positive reaction is obtained apparently in the very earliest stages of the disease, before the appearance of physical signs by which we may estimate the size of the lesion, but when presumably it is very small. But it is definitely upon the present or recent activity of the lesion that the presence of the reaction depends. The alleged tuberculous infection in early life, which has been used as an explanation of the large percentage of positive results obtained in adults by the von Pirquet reaction, does not cause a positive complement-fixation reaction to be given.

3. *The bearing of the results upon the serological uniformity of the human type of tubercle bacillus.*—The

possibility of the existence of several "types" of the bacillus is at present fully appreciated, and much statistical evidence has been collected recently by Dr. J. Brownlee which appears to support this view. But in so far as these experiments have any bearing upon this question the results appear strongly to support the view of the serological uniformity of the human type of the tubercle bacillus.

Conclusions.

The conclusions to be drawn from these results are:

- (1) That in the complement-fixation test we have a specific means of diagnosis of the presence of an active or recently active tuberculous lesion.
- (2) That a negative reaction is as reliable an indication of the absence of such a lesion as a positive reaction is of its presence.
- (3) That a positive reaction in the highest dilution only of complement is just as reliable an indication of the presence of such a lesion as a positive reaction in all three dilutions.

In conclusion, I wish to express my great appreciation for the assistance that my colleagues, Dr. L. S. Burrell and Dr. A. Hope Gosse, have given me in carrying out this work, not only in helping to supply me with material, but also in giving me the value of their opinion on the clinical condition of those cases under their care.

I should also like to thank the other members of the visiting staff of the Brompton Hospital for their permission to make use of the cases under their care, and the residents at the hospital for their assistance.

Clinical Notes :

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF DEFECTIVE SLEEP-SHUNT.

By E. W. SCRIPTURE, M.D.

ONE of the conditions that render sleep possible is the shutting off or shunting of the impressions from the senses. The mechanism is often very efficient. Many people can sleep in the bright sunlight, or close to a railway, or on the hard ground. Most people are not disturbed by daylight in the bedroom, by crowing cocks, or by hard beds. The following case of defective mechanism is perhaps a rare one.

The patient, a man over 50 years of age, as far as his memory goes has suffered as he does now. He is awakened by the first light of dawn. The rattling of a window, a step in the hall, a word spoken in a neighbouring garden, a bird on a distant tree, or any other slight noise will wake him. The pressure of his body on the bed produces, after about 10 minutes, painful sensations that oblige him to turn from one side to the other all night. The sensations from the digestive organs produce constant nightmares. He has been told by various doctors to take bromides or veronal, to drink much beer, to change his diet at night, to put up with the condition as he seemed to keep healthy under it, to stop letting his imagination play the fool with him, and so forth. He has tried all these methods, singly or in combination. Bromides have little effect; veronal was considered dangerous. The beer cure worked excellently in Munich; three pints of lager produced a pleasant sleep with no headache or drowsiness in the morning. A single glass of English beer, however, gives him a disturbed sleep and a muddled head for the day after. Eating produces dreams; starvation wakes him up. An attempt at the attitude of resignation produces a most doleful mental outlook. He underwent a long treatment by hypnotism, with some improvement. Psychoanalysis did not achieve much. He has been forced to rely on his own devices for protection, and he has developed a number of defences. He always sleeps in an attic room with a window away from the road. When travelling he gets a room on the top floor at the back. He wears a special blinder at night made of a silk band stuffed with down; this fits pleasantly and tightly over the eyes. To counteract the joint sensations he formerly used a number of small down pillows packed around the feet and knees. He can now dispense with them by sleeping directly between blankets on a very soft bed.

The defence against noises has been especially difficult. The natural thing would be to stop up the ears. The difficulty lies in finding a substance that is dense enough to keep out the sound and yet so comfortable that the ears do not feel it. Although Ulysses sealed the ears of his sailors with wax when about to pass the sirens, no one seems to have followed up his idea. The antiphones devised before or during the war were hard, uncomfortable substances that could not fit the ears properly; soft things let the sound through. For 30 years this man has experimented with different kinds of wax and similar compounds. The best kind he finds to be the ordinary hard paraffin used for microtome mounts. A pellet held in the fingers soon becomes soft. Placed in the ear it seals it tightly and yet remains so soft that it is not felt.

The condition remains unexplained. One might consider it a reversion to ancestral type of the period when the savage could sleep in safety only if the slightest alarm would wake him. Or it may be that the sleep-shunt mechanism received some injury in early life; the psychoanalyst probably has a suggestion ready.

A CASE OF
ECLAMPSIA IN MIDDLE PREGNANCY,
TREATED BY VAGINAL HYSTEROTOMY; RECOVERY.
By ALECK W. BOURNE, M.B., B.Ch., F.R.C.S. Eng.,
OBSTETRIC SURGEON TO OUT-PATIENTS, ST. MARY'S AND
QUEEN CHARLOTTE'S HOSPITALS.

ECLAMPSIA is a disease not uncommonly met with in the latter weeks of pregnancy, but it is a decidedly rare complication of middle pregnancy. In my patient it occurred at the twenty-fourth week, and this fact, together with other unusual features, has prompted me to record the case.

Mrs. S., a primigravida, was admitted to Queen Charlotte's Hospital on July 28th at 6.30 p.m. The history obtained was that she was quite well until June, when vomiting became severe, associated with swelling of ankles. This cleared up and she was well again until July 26th, two days before admission, when she suddenly developed a severe headache, with stabbing pains in the right eye. This continued during the 27th, and in the afternoon of the 28th she is said to have had three fits. No account of previous renal disease or zymotic infection could be obtained.

On examination she was found to be in a very restless, noisy condition, requiring restraint, and was quite irrational. She presented the appearance of cerebral irritation, following a head injury. The fundus uteri reached the lower border of the umbilicus, and the last menstruation was stated by relatives to have occurred in January. Temperature was 97.6° F., pulse 108, and blood pressure 135 (a dose of veratrine, $\frac{1}{2}$ c.cm., having been given prior to admission to hospital).

There was slight oedema of the legs and face, and the colour was fairly good, without cyanosis. The bladder contained 12 oz. of urine, which gave the following analysis: sp. gr., 1024—reaction, acid; urea, 1.5 per cent.; chlorides, 0.16 per cent.; ammonia, 0.097 per cent.; acetone, nil; diacetic acid, nil; albumin, 0.035 per cent.; deposit—epithelial cells, leucocytes, numerous granular casts.

Having regard for the serious prognosis of eclampsia at so early a date of pregnancy, I decided to evacuate the uterus as soon as the bowel had been thoroughly washed out. Morphine, $\frac{1}{6}$ gr., was given to control the restlessness, but no further dose of veratrine was given, as the blood pressure remained at 135 mm. At 8.45 p.m. I performed vaginal hysterotomy by the usual procedure of reflecting up the bladder above the internal os and making a single incision up the anterior wall of the uterus. Version was done and the foetus easily extracted by the breech. The placenta and membranes having been removed, the incision was sutured with chromic catgut. As haemorrhage was severe and the uterus remained lax during the insertion of the sutures, 1 c.cm. of pituitrin was given and the uterus douched. The foetus weighed 1 lb. 6 oz. and was 10 in. long.

During the night, ten hours after delivery, the sister reported a fit, and the blood pressure had risen to 175 mm., for which $\frac{1}{2}$ c.cm. of veratrine and $\frac{1}{4}$ gr. of morphia were given. The blood tension fell to 156 by 7 a.m. and later to 135 and 140, at which level it remained permanently. There were no more fits, but the patient remained in a restless irrational condition all the next day (29th), but regained complete consciousness on the 30th. A trace of albumin remained until August 10th, but the convalescence was uninterrupted, the temperature never reaching 100° F. The lochial discharge was scanty and disappeared early.

The patient was discharged from hospital on the eighteenth day.

Remarks.

In an analysis of the frequency of eclampsia at different periods of pregnancy Petersen¹ gives the incidence of the disease at the fifth month as only 8 cases in 499, or 1.6 per cent. Among these 8 cases there were no deaths, but among 29 cases occurring at the sixth month the mortality was 34.5 per cent. All the patients were treated by vaginal hysterotomy.

The prognosis of eclampsia in early pregnancy is undoubtedly more serious than in late pregnancy, and it is probable that radical treatment will yield the best results, but at the fifth and sixth months rapid evacuation of the uterus is a different problem from that which obtains at term.

At the end of pregnancy, abdominal Caesarean section offers a safe and rapid method, but when the height of the fundus reaches only to the neighbourhood of the umbilicus the vaginal route alone should be considered. Evacuation by dilatation and digital manipulation can be an extremely difficult and prolonged operation, involving danger to the patient from anaesthetic poisoning, shock, and haemorrhage. Vaginal hysterotomy, however, can be finished in half an hour or less; it involves no tearing of the internal os, there is ample room for the removal of foetus and placenta, and the uterine incision is accessible and easy to suture. For cases which require rapid evacuation of the uterus before the seventh month this operation gives the quickest method, together with the minimum of trauma and shock.

Reviews and Notices of Books.

ANIMAL EXPERIMENTS AND SURGERY.

Hunterian Lectures delivered in February, 1920.
By WALTER G. SPENCER, M.S., F.R.C.S. University
of London Press, Ltd. 1920. Pp. 180. 6s. net.

Mr. Walter G. Spencer's Hunterian lectures on Animal Experiments and Surgery have been recently published in a small book, which should make instructive reading both for surgeons and for the wider public interested in surgical progress. The matter in the lectures was originally gathered in the course of combating the Bill for preventing experiments on dogs, which was laid before Parliament in the summer of 1918 and was eventually defeated. The lectures do not, however, savour of propaganda. The first in the series seeks to present in historical sequence the chief experiments on animals on which the steps in the progress of surgery have been founded; the second describes those experiments which were directed towards the application of surgical methods to the treatment of the individual structures of the body, and includes the transfusion of blood and infusion of various fluids into the circulation, operations on the heart and vessels, anastomosis of the intestine and the treatment of intestinal obstruction, and operations on other abdominal organs; the third deals with more recent refinements in surgery, such as operations on the nerves, brain, ductless glands, and kidneys, and the discoveries upon which is based the treatment of various infective disorders.

To those surgeons who have been content to remain in ignorance of the early history of their craft it will probably come as a surprise to find how much of the pioneer work in surgery was done by Galen in the second century A.D. This writer is chiefly remembered as an anatomist, the account of his numerous original experiments being scattered through his anatomical treatises, and so having been generally overlooked. Yet Galen, whose name is often a catchword for dry antiquarianism, was the originator of surgical operations on the great vessels, heart, brain, bladder, and ureters, as well as being an expert investigator of muscular function and of localisation of function in the brain and spinal cord. On many occasions he defeated the incredulity of opponents by his use of the experimental method, employing for his object various animals, such as dogs, pigs, goats, and monkeys. For centuries all surgical teaching was based on his discoveries, and in several cases the full import of his work was not realised until quite recent years.

The next great experimenter on animals was Vesalius, who, working in the first half of the sixteenth century, supplemented the discoveries of Galen and greatly extended knowledge of physiology and surgery. Some of his most striking experiments were on the heart and lungs, and he was probably the first surgeon to expand a lung artificially after the thorax had been opened. A number of investigators, notably in Italy, followed up the impetus given to experimental research by Galen and Vesalius, and the development of medical science spread by this means to England, Holland, and Denmark during the seventeenth century. In Germany during the eighteenth century Albrecht von Haller was the leading exponent of the value of experiments on animals, but his surgical diffidence was remarkable. "Although entrusted," he wrote, "with a chair of surgery for seventeen years, and although I have frequently given surgical demonstrations, I have none the less never borne to cut a live man lest I should do too much harm." At the same time progress by experiment was going on in England and France, so that in the nineteenth century surgery was able to enter on a new phase, culminating in the discoveries of Pasteur and Lister. Mr. Spencer has, however, found it necessary to emphasise the fact that after the time of Astley Cooper experimentation was much neglected in England, so that we fell behind France and Germany in our knowledge and skill. The statement by Erichsen in 1874 that "surgery has attained its highest plane and

reached its limit of usefulness" appears to have typified the English attitude at that time, though fortunately during the years that followed complacency gave way to progress, due largely to the work of surgeons, such as Horsley and MacEwen.

At the conclusion of his first section Mr. Spencer has rightly drawn attention to the handicap under which surgeons in Great Britain labour in being forbidden to acquire manual skill by means of practice upon animals. Horsley did his best to overcome this in his evidence before the Vivisection Commission in 1907, but without avail. The direct consequence of this is that most surgeons have to acquire their manipulative experience chiefly at the expense of their patients, since it cannot be maintained that operations on the dead body, even if there were to be extended facilities for these, are of much value in the acquisition of technical skill. Mr. Spencer mentions, as outstanding instances of this unsatisfactory state of affairs, the performance of tracheotomy on a child, of the radical cure of a hernia in a baby, and of operations on the eyeball, all of which might readily be learnt by practising on anaesthetised animals. Almost the whole range of abdominal surgery might be included in the same category, and the technique of the surgery of the chest, which is still in its infancy, might sooner reach maturity were British surgeons granted the same opportunities that were enjoyed by Galen 1800 years ago.

It is apparent from the brief summaries contained in Mr. Spencer's second section that very few advances in surgery have been made without the aid of preliminary experiments on animals. The first successful cholecystectomy was performed on a dog by Zambecari in 1680; splenectomy, though practised by the ancients, was not established as a feasible operation until 1872, when Mosler thoroughly investigated the results of the operation in rabbits. Similar instances, too numerous to mention here, are to be found in Mr. Spencer's book; his excellent summaries should be of great service in the future to the trustees of research, and they will also be used for reference by those interested in the historical aspect of the various branches of surgery.

INFECTIOUS DISEASES.

A Practical Text-book. Second edition. By CLAUDE BUCHANAN KER, M.D., F.R.C.P. Edin., Medical Superintendent, City Hospital, Edinburgh, &c. London: Henry Frowde and Hodder and Stoughton. (Oxford Medical Publications.) 1920. Pp. 628. £2 2s.

As ten years have elapsed since the appearance of the first edition of this text-book it may not be amiss to note the exact scope of the work. The title might lead to the expectation of a considerably wider field than is actually covered by the author, who confines himself to the diseases commonly met with in public infectious hospitals in the British Isles. Indeed, in the present volume we find that the one rare disorder dealt with in the former edition, relapsing fever, has been omitted. Cerebro-spinal fever finds a place, but not acute poliomyelitis. A somewhat remarkable omission is that of influenza, which has so recently demonstrated its gravity as an infectious disease.

The first chapter of the book is devoted to a general consideration of infection, immunity, and fever. We note that the author now tends to accept the existence of a connexion between the incubation period of a disease and the phenomena of anaphylaxis suggested by us in a former review of this work. He also admits some scepticism as to the value of the ordinary processes of disinfection of rooms after outbreaks of infective fevers, and notes that equally good results are obtained by simple cleaning and ventilation. The later chapters deal with the individual diseases, and the author has maintained the practical point of view adopted in the former edition, and has only discussed the bacteriology, or rather parasitology, of the affections so far as is necessary from the clinical aspect. It is, indeed, noteworthy that the common specific fevers remain an *opprobrium pathologiæ* in so far as their exciting causes are still unknown. When these are identified, much of the difficulty at present

experienced in distinguishing between measles, rubella, and scarlatina will in all likelihood be a thing of the past, whereas so long as diagnosis depends on mere cutaneous manifestations, it will always remain uncertain, and the question of the existence of some fourth or fifth closely allied affection will admit of no definite answer. In the book before us the author keeps an open mind as to the reality of Dr. Clement Dukes's fourth disease, but considers the evidence so far adduced unconvincing. As an empirical aid to diagnosis Dr. Ker has seen good results in using the Rumpel-Leede test for scarlatina—the production of small petechial spots by application of a fairly tight bandage round the arm. On the other hand, he notes that the Widal test is unreliable as a means of distinguishing typhus from typhoid, as it may often be found positive in the former malady—a somewhat curious condition, as there seems no reason to attribute typhus to any organism related to the *B. typhosus*. In the section on diphtheria we find that tracheotomy is still regarded by the author as preferable to intubation in private cases, as medical aid may not be immediately available if the tube is coughed up. He discusses the value of active immunisation with toxins as a prophylactic for this disease, but there seems little scope for this method in view of the efficacy of a preventive dose of antitoxin in the presence of an epidemic; the latter procedure does not induce the risk of a preliminary negative phase, which seems theoretically probable after an injection of a toxin or vaccine.

We can cordially recommend this book as a useful practical guide to the treatment of infectious fevers in these islands. It embodies the ripe experience of an observant physician, adequately supplemented by a study of recent contemporary literature.

CUNNINGHAM'S MANUAL OF PRACTICAL ANATOMY.

Vol. III. Seventh edition. Head and Neck. Revised and edited by ARTHUR ROBINSON. London: Henry Frowde and Hodder and Stoughton. 1920. Pp. 568. 12s. 6d.

THIS is the remaining volume of an edition which we have already noticed, and is a worthy companion of the two other members. The illustrations are again outstanding features, and include many radiographs. The three volumes make a beautiful and complete work of reference, possibly more suitable for functioning in that capacity than for the needs of the average student, who has little time to loiter in the pleasant by-ways of anatomy.

THE TREATMENT OF SYPHILIS.

By H. SHERIDAN BAKETEL, A.M., M.D. New York: The Macmillan Company. 1920. Pp. 167. 13s.

THE author gives a clear account of the treatment of syphilis, with special regard to intravenous medication, the technique of which is too often neglected in text-books. This deficiency Dr. Baketel has remedied by his detailed account of the methods employed in the clinics under his charge. The standard the author sets is a high one. Whilst it affords an ideal at which every syphilologist should aim, we must confess that the time demanded for the carrying out of the excellent technique described by Dr. Baketel makes it difficult of attainment in many of the overworked and understaffed clinics of this country.

A clear and interesting précis of the history of arsphenamin is given in the opening chapters. Dr. Baketel traces the progress of arsenical medication from the days of atoxyl, and gives a brief account of the chemistry of arsenic compounds. Methods of administering mercury and iodides are also described. In the later chapters the treatment of congenital, visceral, and nervous syphilis is discussed, as also the question of reactions and accidents following the use of arsphenamin. Finally, the difficult subjects of cure and of marriage are approached. With regard to the latter, the author lays down the rule that no man should be allowed to marry until repeated examinations of blood and cerebro-spinal fluid have demonstrated

that the spirochaetes have been absolutely eliminated from the system. "A man with a positive Wassermann, even though it be caused by an aortitis or a lesion of the spinal cord, should not marry or endeavour to procreate."

The book is well illustrated, and every step in the procedure of intravenous injection can be followed in the plates. It is altogether an excellent guide to anyone desirous of attaining a good technique in the treatment of syphilis.

AIDS TO OSTEOLOGY.

Second edition. By PHILIP TURNER, B.Sc., M.B., M.S., F.R.C.S. Students' Aid Series. London: Baillière, Tindall, and Cox. 1920. Pp. 187. 4s. 6d.

As a concise summary of the main facts in human osteology this little book is a good member of the series to which it belongs. It will, doubtless, prove of value to the ordinary student who wishes to revise the subject of "bones" before an examination. A large amount of information is compressed into a small space; the descriptions are formal, and the English nomenclature is used. We must point out, however, that Albrecht's suggestions about the ossification and formation of the premaxilla are discredited, and the modern teaching of the development of the maxilla and mandible differs from that given in this book.

DUTIES OF SISTERS IN SMALL HOSPITALS.

By FELICE NORTON. London: Baillière, Tindall and Cox. 1920. Pp. viii. + 75. 4s. 6d.

THE practical experience gained in a small hospital may be a priceless asset in a nurse's career, but whether this is so or not depends largely on the tact, efficiency, and ethical standard maintained by the sisters in it. Miss Norton's book may serve as a model to those upon whom the training of probationers devolves. The author has incorporated within the limits which she has set herself sound and practical advice, and we recommend her injunctions to every nurse who is about to assume the responsibilities of a sister's post.

X RAY ATLAS OF THE SYSTEMIC ARTERIES OF THE HUMAN BODY.

By H. C. ORRIN, O.B.E., F.R.C.S. Edin. London: Baillière, Tindall, and Cox. 1920. Pp. 92. 12s. 6d.

THE author has devoted a large amount of time and ingenuity to the production of the very beautiful plates which form the basis of this book, and he has demonstrated the possibility of injecting, for X ray work, even the smallest arterial branches; this is particularly well seen in the photograph of an adult hand. The work, as a whole, was done on a foetus owing to difficulty in procuring an adult cadaver. While admitting at once the clearness and value of the plates, the success of the author's methods, and the interest of the relations thus brought out between the vessels and the skeleton, we nevertheless confess that this sort of work seems to us to be of relatively little value from an anatomical standpoint. The plates show nothing that is not known and taught by the usual methods; in fact, they necessarily show an incomplete picture. Surgically the relations between bones and vessels are not by any means the only important ones, and X ray work, so far as it goes at present, cannot give an adequate idea of the relations existing between the arteries and the soft parts. We doubt whether the mere demonstration of continuity between vessels is, from an anatomical point of view, of importance sufficient to outweigh the absence of all those other "relations" which make up a knowledge of the anatomy of the arteries; there is a tendency at present to magnify the value of X ray work in anatomy, and to allow it to assume in this subject a position to which it has no justifiable right. This said, we can commend without further reserve a book which could be placed with advantage in the hands of a student together with his ordinary anatomical manuals. The letterpress accompanying the plates is a concise summary of distributions and branches.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 25, 1920.

Post-Graduate Medical Study.

A FEW weeks ago our Vienna correspondent wrote of a series of post-graduate lectures to be delivered in that city during the present summer months, covering the whole range of medical and surgical knowledge and open to medical graduates of all countries. He added that English readers would be interested to learn that American doctors were coming to Vienna and that a considerable number of them had already booked places for the approaching winter term. Our readers will therefore be not unprepared for the item of news which Mr. GEORGE E. MACLEAN, director for England of the American University Union in Europe, communicates to our correspondence columns. A committee in Chicago has organised an excursion for physicians to go to Vienna for study in the way that American physicians were accustomed to do before the war. No one, we think, can grudge the improvement in economic conditions which makes it just possible for professors and tutors to keep themselves from starvation by giving of their best to medical brethren from other lands; least of all this country, which, next to America, has contributed so largely to the rehabilitation of its Austrian colleagues. A multitude of grateful pupils will welcome any sign that medicine begins to feel its feet again in Vienna.

But this is not to say that post-graduate medical study on the continent of Europe will have the same easy pull over the attractions provided in this country that it had a decade or two ago, when the continental habit was formed. Everything points the other way. The arrangements for medical education in this country are changing like a kaleidoscope, and the alteration would be astounding to anyone who could picture vividly the difference between the mental pabulum and the facilities offered in 1920 and those of 1900, when post-graduate instruction had practically not come into being. Hardly a week now passes without the announcement in our columns of some new and attractive object of study for those who have obtained a legal qualification. Last week it was a course for general practitioners to be given at St. Andrews under the direction of Sir JAMES MACKENZIE; the issue before it was a post-graduate week at Oxford in early October to be addressed by Sir ARCHIBALD GARROD and Professor G. DREYER. Successful post-graduate courses have been conducted during the past year at Glasgow, Sheffield, Birmingham, Manchester, and other university centres. It is the gracious task of the Fellowship of Medicine, associated with the Post-Graduate Medical Association, to be the centre of exchange for all existing facilities and for others as they come into being. It should be a matter of common knowledge that a Fellowship ticket costing four guineas a month entitles the holder to attend the clinical practice, including practical demonstrations and laboratory work, at the 12 great London medical schools and at 25 special hospitals in the metropolitan area. The weekly bulletin of the Fellowship contains a time-table which shows at a glance where and by whom the classes and demonstrations

are given. It is, of course, an essential condition of a successful ticket office, on the one hand, that the functions for which tickets are issued should actually take place, and, on the other, that when they do take place visitors should be present in sufficient numbers to justify the trouble which the performers have taken. Complaints on both these scores have reached us from time to time. During the holiday season especially it is natural that teachers of distinction should not be found at their posts, but it has happened—and it should not happen—that fixtures announced in the bulletin have not taken place. Other demonstrations arranged with care and forethought have remained practically unvisited. It is easier to see and regret these difficulties than to avoid them. In any case they are but the ripples on the surface of a great volume of arrangements satisfactory alike to teacher and taught.

It is in this respect that the continental plan of a special and detailed scheme of post-graduate study in all its branches has an apparent advantage. Such courses in Vienna are arranged solely and entirely for the convenience of graduate students. Patients are brought from all parts of the city to a central clearing-house, where they are classified and arranged without any particular consideration for the human material. Medicine is not tending that way in this country, where teacher, student, and patient form a trio, each of whose needs is considered and subordinated if need be to those of the others. The continental plan, as we may briefly call it, does away with the social and economic setting of the patient, a factor of ever-growing interest and importance. It would be quite possible to build up such a system in London, and when it was done it would resemble the annual view-day, which is such a travesty of normal hospital routine. We offer a word of encouragement to those who have suffered from the minor inconveniences of sight-seeing. The sights are there right enough, but each student must be content to be in a measure his own cicerone. His reward will be that when he gets there he sees the real thing and not a puppet-show. The Fellowship of Medicine is on the right lines in following an indigenous plan. Development is proceeding. The attachment to each medical school of a complete post-graduate scheme with clinical assistantship appointments for practitioners is undoubtedly the ideal to be aimed at, and will come in the fullness of time. The concentration of post-graduate teaching around some of the new clinical units in our London schools is, as our special article last week indicated, becoming an actual reality. Further opportunities will naturally grow out of the work in hospitals and clinics now steadily being created throughout the country. Soon we shall have nothing to fear from comparisons.

End-results in Nerve Injuries.

Sir WILLIAM THORBURN concluded an introductory address to the Section of Surgery at the annual meeting of the British Medical Association with the words: "If a surgeon obtains 50 per cent. of really good economic recoveries after secondary nerve suture he is doing well; if he obtains 75 per cent. of such recoveries his work is both brilliant and fortunate." A careful study of his address, which appears in our present issue, shows that he did not himself look at the picture of nerve surgery through rose-coloured glasses; and, in

view of the many patients attending hospital at the present day after nerve suture, it is clear that his reservations are justified. The question which indeed arises is whether Sir WILLIAM THORBURN is himself not optimistic—whether his “50 per cent. really good economic recoveries” is possible of realisation, in consideration of the severity of gunshot injuries of nerves. It is everyday experience that after suture of the musculo-spiral nerve such a recovery rate may be anticipated, and an approximate but lesser degree of recovery after operation on the sciatic nerve, but the observed results after suture of the median, and more especially the ulnar, nerves seem to show that the surgeon must be both brilliant and fortunate to obtain such good numerical results. Few branches of surgery require more anatomical knowledge and greater specialised skill than nerve surgery. The results hinge on detail—cleanliness, hæmostasis, delicacy in handling the nerve itself, and an exact knowledge as to how the attendant difficulties (and there are many) are to be overcome. Some of the unfavourable results may be due to want of this exact skill and knowledge. The busy surgeon is still apt to regard the case as finished when the stitches are out, regardless of the fact that the preliminary stage alone is completed. But even after making such allowances we must admit that, with the exception of the musculo-spiral and sciatic nerves, the results of secondary nerve suture are disappointing. Before the war the idea was prevalent that end-to-end suture was, when possible, desirable. We know now that end-to-end suture must be striven for in the face of all prevailing difficulties. It is the one method which may give a reasonable, perhaps good, functional result. All other methods, in spite of some few successful cases reported, are disappointing. We fear that an investigation of cases under treatment at the various London hospitals at the present time would show that our less sanguine views are justified. It may be argued that the patients attending orthopædic and electrotherapeutic centres are merely the failures, but unquestionably many who are there are striving to obtain a better economic result. It should be clearly borne in mind that a patient suffering from a divided nerve of the size and nature of the median or sciatic is economically useless, and the operator would be wise to study nerve surgery in all its details before he advises and carries out operative procedures. We would add also that all those who are interested in nerve surgery would benefit greatly by studying the many cases of nerve injury attending the out-patient departments of pensions hospitals.

Wilhelm Wundt, 1832-1920.

WILHELM WUNDT was born near Mannheim in 1832. He first devoted himself to the study of medicine, becoming privat-dozent in physiology under HELMHOLTZ in Heidelberg at the age of 26. Two years later he published his *Theory of Sense-perception*, this forming his first approach towards philosophy, to which he had hitherto paid as little attention as does any ordinary student of medicine. This contribution sketched out a programme for the experimental treatment of psychology that WUNDT afterwards did so much to foster. Hitherto experiments bearing on this youngest of the children of philosophy had been made exclusively by physiologists for physiological

purposes, or in the case of FROHNER for its psycho-physical interest. Under the stimulus of HELMHOLTZ'S great works on hearing and vision WUNDT'S psychological studies led to his lectures on the human and animal mind (1863), in which he made his first reference to the bearing of ethnology on psychology. The first edition of his *Physiological Psychology* appeared in the following year. After a brief activity in Zurich as professor of “inductive philosophy,” WUNDT was called to Leipzig, where he remained till his death. As he declared in his introductory lecture there, his constant effort was to construct a unitary vision of the world in all its aspects, but—unlike many philosophies of the past—in constant affiliation with the methods and results of all the sciences. In view of the then recent collapse of the Hegelian philosophy, which presumed to construct the universe and all its history out of the self and its logic, that effort showed a wise restraint, calculated to restore philosophy to its due place of honour among the mental and spiritual products of man's urge towards thought. But if the source and methods of previous German philosophy were thus abandoned, the range and bulk of production taken by its professor as an ideal of attainment was rather increased. WUNDT traversed the whole field of philosophy in long works of numerous volumes, as well as in countless papers in journals. His *Physiological Psychology* reached its sixth edition in three large volumes in 1908. His *Logic* appeared in 1880-83, and reached its third edition in three volumes in 1906. There are besides: *Ethics*, 1886—third edition, two volumes, 1903; *System of Philosophy*, 1889—third edition, 1907; *Anthropology*, in six volumes, from 1900 on—now in second and third editions; *The Sensuous and Supersensuous World*, 1914. His output was enormous.

The first institute of experimental psychology was founded in Leipzig by WUNDT in 1879. From it proceeded a great number of the senior professors of psychology of the present day. In America his pupils are specially numerous, of whom TITCHENER has perhaps come nearest to the stature of his teacher. The work of WUNDT'S laboratory is conserved in his “*Philosophische Studien*,” and in the following “*Psychologische Studien*,” as well as in journals. WUNDT'S psychology embodied the results of these investigations, far too exclusively indeed, as prominent German psychologists have admitted. His exposition was practically a psychology of the Leipzig studies, which have too often failed to stand the test of rigorous examination. STUMPF, the foremost exponent of the psychology of hearing, made short work of their efforts in audition. For this reason WUNDT'S labours in psychology have had less influence than their bulk would suggest. The citadel of his laboratory was so built that for most travellers at least the gate of orthodoxy was the only road to graduation or study. That, of course, is so universal as almost to be inevitable in what is called a school in philosophical circles, and psychology has not shaken free of this pernicious tradition. In his effort to make all the sciences—natural, mental, and logical—converge to form an approximately and temporarily complete philosophical system WUNDT'S philosophy has gained the greatest respect, and is on the safest lines, however striking the efforts of one-sided extremists may be—when they are successful. The man who stakes his all on a conviction risks total obscurity for the chance

of progress and immortality, while enormous mediocrity can at most oppress us only until the sciences roll us away from it. Some of WUNDT's colleagues have compared him, as a mind uniting in itself all the knowledge of its time, with ARISTOTLE or LEIBNITZ. But there was not in him anything so unique and distinctive as there was in LEIBNITZ. The thought of centuries will hardly be compelled to focus itself on WUNDT for one of its characteristic and insuppressible synthetic possibilities.

WUNDT was of pleasing and gracious personality. His style of lecturing was objective and plain, his conversation courteous and direct. He was severely abstemious, living solely for intellectual capacity. His lectures were crowded to the limits of the auditorium, as he was an outstanding feature for all Leipzig students. The year 1914 was a difficult time for a philosopher. To the regret of those who knew him, the intellectual conscience that had often allowed his zeal for production to outrun his care for exactitude and his fair judgment permitted WUNDT to write about the spirit of British and French philosophy in a way calculated to bring them into contempt. France had sold her soul for honour, England for money and social power, while Germany alone was striving for an ideal. Even NIETZSCHE was cited as a witness. Thus did philosophy fail the octogenarian philosopher.

Annotations.

"Ne quid nimis."

WAR-ADAPTED ASYLUMS.

THE History of the Asylum War Hospitals in England and Wales, presented as a report to the Home Secretary by Sir Marriott Cooke and Dr. C. Hubert Bond (H.M. Stationery Office. Price 9d.), sets forth the services rendered to the wounded and sick during the war by the asylum authorities throughout England and Wales under the direction of the Board of Control. During 1915, from certain selected asylums the insane patients were removed and the institutions so vacated were adapted, equipped, and organised as general medical and surgical military hospitals. The scheme when fully developed supplied 24 hospitals which, without exception, were acknowledged by all the many expert authorities, military and civil, and other competent judges who inspected them to have afforded facilities for treatment in all respects equivalent to those available at the best military and civil hospitals in the country. These 24 hospitals provided, with some hutments, as many as 27,778 permanent beds; and when the extension by camps and the temporary beds used in times of special pressure are taken into consideration, could accommodate over 31,000 patients. The number of patients treated in them to the date of this report has been 482,949, approximately equivalent to one-sixth of the total number of sick and wounded men from all fronts during the war. The selection of asylums was based upon the principles that they should be of comparatively modern construction and suitable for use as general hospitals; that they should be accessible by rail and in proximity to large towns where physicians and surgeons should be readily available; that the asylums should be arranged, according to their geographical situation, in nine groups, and that from among each group one asylum should be converted into a war hospital, while the other asylums in the group should receive all the insane patients belonging to the vacated asylum; and that although the insane patients might suffer some inconvenience, the receiving asylums might for the time be overcrowded to the extent of 20 per cent. of their normal accommodation. In the

short space of a few weeks the nine asylums had been cleared of their insane patients, excepting a few who were to carry on the farm work or who were too ill to move. This rapid transference of some 12,000 patients, including many dangerous and violent cases and many who were aged and feeble, was effected without any untoward incident. It is sad, but consoling, to learn that many of the patients exhibited sorrow on being obliged to leave institutions which had, in some instances, been their homes for years, and that the mutual regret shown by patients and by members of the staffs on parting was pathetic.

The adaptation, equipment, and organisation of the asylums as war hospitals were undertaken by the visiting committees of the several vacated asylums, as well as the collection of the requisite additional staff and the carrying on of the business side of the administration of the hospital, including the settlement of contracts for the supply of food and necessities for patients and staffs. The adaptation included the removal of everything in the buildings which might have been objectionably reminiscent of their normal purpose, the provision of operating-rooms, of X ray apparatus, accommodation for additional staff and stores, and occasionally the alteration of roads to provide easier access for ambulances. In the matter of the staffs the medical superintendent became officer commanding and administrator; the senior assistant medical officer became the registrar and usually acted as deputy to the officer commanding; the other assistant medical officers, ineligible for foreign service, or not as yet released for it, were given posts on the medical staff of the hospital. Where the matron had had full training in a general hospital she was made matron of the hospital. All the asylum nurses, however great their experience in nursing bodily illness among insane patients, were classed as probationers, and had to work—sometimes in wards of which they themselves had had charge—under the sisters and trained hospital nurses, a trying position for them. To the male asylum attendants was given the orderly work in the wards and elsewhere in the hospital, as well as the duty of acting as male nurses when necessary. The services of the best operating surgeons and physicians in the locality of each hospital were secured as visiting surgeons and physicians, while to the surgical and medical divisions of the hospital were appointed a chief resident surgeon and a chief resident physician.

As the war went on the original number of nine hospitals was added to, and ultimately 24 asylums and kindred institutions were being used as military hospitals, one of them as an United States Base Hospital. In addition to the enormous number of physically sick and wounded patients the large total of 38,440 patients suffering from mental breakdown or nervous diseases had up to May 1st, 1920, been treated either in a section of one or other of the war hospitals or in the seven smaller hospitals, most of which were established later on, and from their inception devoted exclusively to the treatment of soldiers suffering from mental and nervous complaints. Of the 24 hospitals, 17 have now been closed down, and of the hospitals still in operation probably all but four will have closed by the end of this year.

The asylum authorities and officers have a right to look back with satisfaction on the splendid work they were able to do for the country in general, and the sick and wounded in particular, at a time of urgent need.

THE FLUCTUATION OF SCARLET FEVER.

CONSIDERABLE attention has been drawn during the past few weeks in more than one journal to the annual summary issued by the Ministry of Health in respect of the number of notifications in each sanitary district of a variety of infectious disease. Interest has been riveted particularly on two diseases—scarlet fever, the prevalence of which, after an appreciable increase in 1913 and 1914, showed a remarkable decrease in 1917 and 1918, followed by a rise in 1919; and diphtheria, which after some increase in 1914 and 1915, showed no similar reduction in the later war

years. A variety of suggestions have been offered in the public press to explain these perplexing variations in one disease and the equally perplexing contrast with the other common infectious disease, the control of which is commonly regarded as no more difficult than is that of the former. Was the drop in the incidence of scarlet fever in the later years of the war the result of the war, in some way which cannot at present be defined—possibly, for example, by the diminution in the crowding of children, by the transfer of the men to camps and of many women to the residential quarters connected with munition works? Was the incidence of scarlet fever affected by some variation in the prevalence of fleas, which have been suggested by one well-known medical officer of health as a possible channel of infection? One phenomenon, however, appears to have been ignored in many of the comments on this vagary of scarlet fever—that is, the fact that there is a cyclical variation in the prevalence of most of the acute infectious diseases, which was formerly recognised from study of the records of deaths, and which can now to some extent be noted in the national statistics of notifications, which have been collected year by year since 1911. The statistics of incidence, as apart from mortality, do not extend back for a sufficient number of years for the curve of varying prevalence to be clearly indicated. The figures of incidence both for scarlet fever and for diphtheria given by the Registrar-General do, however, distinctly suggest such cyclical variation, and it appears reasonable to assign to the factors behind these normal variations a large responsibility for the low rates of incidence of scarlet fever in 1917 and 1918, which appear to correspond to the trough of the wave between 1914 and the next maximum, possibly to be attained in 1920 or 1921. This in itself is obviously not an explanation of the phenomenon, and no explanation of the changing cycles of prevalence can yet be given, though doubtless some part is played by a variety of known influences. Among these may be mentioned variations in the susceptibility of the population to infection, the susceptibility increasing and approaching steadily towards the point of explosion as the period from the previous outbreak lengthens. Again, it is conceivable that there may be a periodic alteration in the virulence of the organism causing the infection. It is further recognised that the degree of prevalence of the infectious diseases is closely bound up with variations in the conditions of soil and air—variations in the level of underground water, in the earth temperature, and in air humidity. We still await the wide and detailed exposition of the true bearing of these and other influences on the prevalence of the infectious diseases. Meanwhile, we can happily yet proceed, in the hope of an appreciable measure of success, with the business of curbing their capricious visitations.

CHRONIC SEPTIC SPLENOMEGALY.

In his first Lumleian lecture on the War Experiences of a Physician, printed in THE LANCET of Sept. 11th, Sir John Rose Bradford described an obscure and rare disease of which he had seen two, possibly three, instances. This malady was characterised by a febrile illness having considerable resemblance to enteric fever and lasting several weeks, during which the spleen slowly increased in size to a dimension comparable to that reached in ordinary spleno-medullary leukaemia. Indeed the cases presented considerable likeness to this disease, but differed, in that, after an illness of many weeks, the pyrexia declined, and the spleen slowly returned to normal. Sir J. Rose Bradford states that the nature of these cases is obscure; certain tropical affections could all be excluded, and the search for parasites was negative. They may, however, bear relationship to some cases recently published by Dr. Gordon Ward¹ under the title of "Chronic Septic Splenomegaly." From the large group of splenic anæmias he separates these cases into a class the aetiology of which is not specific, but which, according

to him, is well recognised in American literature. The condition may follow the invasion of any of a large number of organisms, but there is reason to suppose that the streptococcus is most frequently responsible, and the primary foci of invasion are usually the intestines, pelvic organs, and nasal cavities. According to Dr. Ward, the cases described in medical literature fall under the following groups: (a) Egyptian Splenomegaly, described by Richard and Day, Archibald, Nicolle, &c.; (b) Endocarditis Maligna, described by Parkes Weber, Riesman, &c.; (c) Oral Sepsis with Splenomegaly (Essex Wynter); (d) Enteritis with Splenomegaly (Hollins); and (e) others associated with bacillary dysentery, parametric abscess, dental sepsis, and infection of the antrum. The diagnosis is not difficult; blood examination excludes leukaemia, there is no jaundice, nor are there enlarged lymphatic glands. Splenic puncture excludes kala-azar, Gaucher's disease and malaria, while Wassermann's reaction excludes syphilis. Five cases are described by Dr. Ward, in which there was enlargement of the spleen associated with dysentery, parametric abscess, and infection of the antrum of Highmore, the enlargement disappearing when these conditions were cured. In Sir J. Rose Bradford's cases blood examination revealed a condition similar to that seen in splenic anæmia, a diminution in the number of red cells, and a considerable leucopenia, the white count falling to 3000. Dr. Ward gives a very fully detailed account of the blood examination in his five cases. The number of red cells varied between 2,825,000 and 6,670,000, and the leucocytes between 3200 and 17,800; nucleated red cells were rarely seen; polychromatophilia was constant, but by no means marked. This difference in the blood examination seems to us rather striking, and further evidence will be necessary before deciding that Sir J. Rose Bradford's cases and those of Dr. Ward come under precisely the same category.

PHARMACO-ENDOCRINE THERAPY.

AN official report of the twenty-first annual meeting of the American Therapeutic Society, held at the College of Physicians, Philadelphia, last May, has just reached us, from which it is evident that the presidential address, by Dr. Charles E. de M. Sajous, of Philadelphia, was of more than passing interest. It was in effect a powerful plea for renewal of interest in the science of therapeutics, which appears to be suffering from neglect in America at the present time. His main argument may be briefly recapitulated.

The salvation of therapeutics would depend, in Dr. Sajous's view, upon the degree of curative efficiency it could be made to attain. If the pharmacologist concentrated his efforts upon its main purpose, the cure of disease, by studying the influence of drugs upon our defensive functions, he would stimulate endeavour on all sides. Great confusion in experimental endocrinology and the lack of agreement among workers in this field had led Dr. Sajous to work independently, seeking what light clinical and experimental data might throw upon the subject. His views, derived from the clinic, were often in disagreement with those of physiologists and pharmacologists. With regard to the adrenals, in his opinion clinical experience with the human subject did not bear out the statements of physiologists that therapeutic doses of adrenalin had an inhibitory effect on the functions of the gastro-intestinal canal; in fact, the effect was often quite the opposite. The supposed blood pressure-raising power of adrenalin also proved misleading. Indeed, one of his workers found that if there was one thing that adrenalin *did not* do it was to raise blood pressure.

Dr. Sajous's studies, in accordance with those of other workers, had convinced him that absorption of oxygen from the air in the pulmonary alveoli necessitated in the pulmonary circulation some substance capable of actually appropriating this gas. It was suspected that this substance was some kind of internal secretion, and clinical studies in over one hundred diseases pointed to the adrenals as the source of this secretion, which, after entering the vena cava and passing through the right heart, finally reached the pulmonary alveoli with the venous blood. Here it probably became part of the hæmoglobin, converting it into oxyhæmoglobin. Considerable evidence, both direct and indirect, showed that the adrenal secretion influenced general oxidation and metabolism, increasing the intake of oxygen and the output of carbon-

¹ Archivos de cardiologia y hematologia, May-June, 1920.

dioxide. The adrenin present in the hæmoglobin was taken as the real measure of adrenin in the blood—not what the adrenal bodies secrete, which might be nil under normal conditions and excessive under excitement or stimulation. Dr. Sajous suggested that pharmaco-endocrinology might be studied in this connexion as having a bearing on the manner in which drugs influence the functional activity of the ductless glands. If, therefore, with some drug one could enhance the action of the adrenals one could, at will, increase not only respiratory activity but also tissue metabolism, the foundation of all functions. Strychnine he considered the most active suprarenal stimulant. Others existed, such as cocaine in small doses, and digitalis and quebracho were partial excitants of adrenal activity, caffeine, tea, and coffee also possessing this power when used in moderation. Having discussed adrenal stimulation, Dr. Sajous turned to the question of how to control excessive activity of the adrenals. Various disorders, sexual, muscular, and cutaneous, were traceable to hyperadrenia. This caused in some cases a pseudo-type of high blood pressure, due to excessive constriction of all arterioles, thus producing arterio-sclerosis. The antagonists to this hyperfunction of the adrenals were the nitrites. Persistent hyperadrenia was the cause of the high blood pressure in those cases termed pseudo-angina pectoris, and nitrites combined with dietetic regulation rapidly removed this disorder.

Another potent resource at the disposal of therapeutics was the thyroid gland, with its influence on the katabolic phase of metabolism in the breaking down of fats and soft tissues. A further function preeminently attributable to the thyroid was its immunological activity, so active at times that it destroyed not only bacteria and their toxins but the tissues themselves. The over-active thyroid was indeed capable of destroying both body and mind. Dr. Sajous stated that in dementia præcox the phosphorised cerebral cell fats had been katabolised by the thyroid hormone secreted to destroy the pathogenic agent, usually of intestinal origin. In hypothyroidism, on the other hand, the patient was highly sensitive to infections and succumbed promptly thereto unless protected by thyroid therapy.

The influence of drugs on the thyroid gland, Dr. Sajous concluded, would have to be studied in regard to the body's defensive functions. The iodides, by stimulating the activity of the thyroid gland, added to the body's antitoxic and bactericidal functions. Besides the iodides, calomel, in very small doses—not more than 1/12 gr.—was a powerful defensive agent. Given in these quantities calomel, by its thyro-activation, had been effective in checking epidemics of diphtheria, probably by increasing the flow of antibodies in the blood. Such examples sufficed to illustrate the resources of pharmaco-endocrinology. Excitants of the ductless glands could be used to abort disease by stimulating antibodies, and depressants of these organs could be used to check exuberant activities which destroyed both mind and body. Organo-therapy indicated the influence of endocrines upon morbid processes; and pharmaco-endocrine therapy revealed their true importance as weapons against disease.

Dr. Sajous has himself made important contributions to the subject of which he writes, and his views demand attention. In an appeal for the endowment of a Chair of Pharmacology at St. Mary's Hospital Medical School, it is pointed out that there is only one complete pharmacological institute in London, and even this is dissociated from any hospital. The neglect of the systematic study in this country of the therapeutics of the endocrines by recognised pharmacological methods is probably also in large degree due to the difficulties of standardisation. When these have been surmounted—and the matter is under the present consideration of a committee appointed¹ last May by the Minister of Health—the study of endocrinology may be expected to attract fresh attention and important results may ensue.

INFLUENZAL MASTOIDITIS.

THROUGHOUT last winter and spring, but especially during the spring months, there occurred an abnormal number of cases of acute otitis media in which the sequence of nasopharyngeal infection and infection of the middle ear has been obscure or so foreshortened in time that the otitis has been the first observed occurrence. The extreme virulence of the otitis has been remarkable in many of these cases, so that some of them have appeared septicæmic almost from the first hour, and nearly all have shown a quite abnormal degree of intoxication. Where a definite catarrh has been present it has been of that febrile type which constitutes,

when epidemic, an "influenza." The bacteriology of the middle-ear process is streptococcal. A precocious involvement of the mastoid has been common, and has often been discovered before there were any evidences of mastoid infection clinically, the case being explored simply on the strength of the patient's very grave general condition and the otitis. It has been remarked in addition that where the initial stages of the otitis were got through without mastoid exploration there has still been an unusual proportion of cases in which the continuous presence of profuse discharge, often without any other sign, has led to the exploration of the mastoid and the discovery of extensive infection and pus formation. In our issue of July 31st (p. 241) Mr. F. F. Muecke and Dr. C. Grantham-Hill described a number of these milder cases of symptomless "influenzal mastoiditis." The absence of obvious signs of mastoid suppuration, leading in many cases to delay of operative treatment, has, however, occasioned a quite unusual proportion of the graver intracranial complications. A recurrence of otitis media of this severe type is probable during the coming winter months, and it will be necessary to keep the matter in mind if the occurrence of unnecessary catastrophes is to be avoided. The indications for operation, judging by last year's experience, should be, firstly, the presence of grave general intoxication in any case of acute otitis media; second, the persistence of profuse discharge even without any obvious malaise and in the absence even of any mastoid tenderness or periosteal thickening. In nearly all such cases a valuable indication of suppuration in the antrum will be found in the swelling of the periosteum and integument of the deepest part of the postero-superior part of the wall of the bony external meatus. Where this condition is present the mastoid should be opened without delay.

GASTRIC POLYPOSIS.

ACCORDING to Dr. Ernest S. Du Bray,¹ of the University of California, who reports an illustrative case, confirmed cases of gastric polyposis are comparatively uncommon. He suggests that some of the vague and obscure conditions of the stomach which have been diagnosed as chronic gastritis or gastric neurosis may, on further investigation, prove to be examples of benign tumours of the gastric wall. The term "gastric polyposis" includes adenomas, fibromas, lipomas, and papillomas, which may all form polypoid tumours, in which sometimes the connective tissue predominates and at other times the glandular elements. The most important primary benign tumours of the stomach are polyadenoma and papilloma, the others being extremely rare. Nothing definite is known about the cause of gastric polyposis, but it is frequently associated with other diseases, such as gastritis, hypertensive cardio-vascular disease, and syphilis. It is commonest in men past middle age. There are no pathognomonic symptoms, although there are sometimes suggestive evidences of the disease. Clinical manifestations depend principally on the size, position, and nature of the growth, and especially on its relation to the pyloric end of the stomach. Non-pedunculated masses on the greater curvature may remain latent or more commonly produce vague epigastric symptoms, followed by a desire to belch and eventually to vomit. The symptoms do not appear to have any relation to meals. The vomit contains an excessive amount of mucus, in which, as in Meyer's case, a polyp may sometimes be found and enable a pre-operative diagnosis to be made. There is usually achylia gastrica or hypo-acidity. Pedunculated and less commonly non-pedunculated growths near the pylorus may prolapse and give rise to partial or complete pyloric obstruction. Hæmorrhage due to the great vascularity of the tumours is frequent, but remains long unrecognised. Occult blood will be found in the fasting contents of the stomach and in the stools. The general nutrition, weight, and blood picture are less affected, as a rule, than in

¹ THE LANCET, 1920, i., 974.

¹ Archives of Internal Medicine, August 15th, 1920.

carcinoma. Generally speaking, palpable masses are commoner in those cases in which the growth is large. Long duration of the symptoms with little or no change in the patient's general health is strong evidence against the presence of malignant disease and should suggest the possibility of a benign tumour. Dr. Du Bray's case occurred in a man, aged 48, who had a history of epigastric pain and belching with loss of weight of six months' duration. Apart from epigastric tenderness, physical signs were negative. The absence of free hydrochloric acid in the gastric juice and the presence of occult blood in the stools, together with the fluoroscopic picture, which showed a large, clear-cut defect in the greater curvature, suggested a diagnosis of gastric carcinoma. Exploratory laparotomy revealed a broad-based papillomatous tumour in the greater curvature of the stomach. The tumour was excised, and the patient when seen six months later had had no recurrence of his symptoms.

THE PROPERTIES OF SERPENT VENOM.

WE have in the *Tropical Diseases Bulletin*, issued under the direction of the honorary managing committee of the Tropical Diseases Bureau, a useful and practical Centralblatt in a branch of medicine of steadily growing importance. The August number of the *Bulletin* contains a review of a series of papers recording the results of exhaustive investigations on the properties of serpent venoms. The details were published by B. A. Houssay, J. Negrette, and A. Sordelli in the Review of the Institute of Bacteriology (Buenos Aires), and deal chiefly with American species of serpents, while including also Australian, Asian, and one European species. The action on carbohydrates, fats, and lecithin of certain venoms was first investigated. These venoms are summarised as having no amylolytic action and as being almost inert, with one exception, against neutral fats, but as saponifying lecithin with evidence of a strong hæmolytic power. This ability to split lecithin is favoured by salts of calcium and by normal serum, and may either be thermolabile, or thermostable to a varying extent. These venoms also curdle milk; their properties are lost by filtration, by agitation with animal charcoal, and by heating (70° C.), and slightly impaired by horse-serum. Though the respective antivenines are specific they are to a certain extent congeneric. The varying action on proteins of the same venoms is then discussed. The proteolytic action is much weaker than that of trypsin, and is not exercised on solid proteins, except on fibrin in the presence of salt water. The proteolytic venoms generally retard coagulation by heating; they alter and then hydrolyse the proteins of serum, change dissolved casein so that it is no longer precipitated by acetic acid, and liquefy gelatin. The proteolytic property is distinct from the coagulant, agglutinative, toxic, and hæmolytic properties. The special diastatic properties of various organs and tissues of *Lachesis alternatus* have been investigated in detail and a certain amount of lecithinase (or fat-splitting) and amylolytic action has been discovered in most of them; the pancreas and liver alone show a weak inversive power and a weak lipolytic action on oil. No proteolytic action could be demonstrated in these tissues. The venoms of two Australian species, *Pseudechis porphyriacus* and *Notechis scutatus*, and two Indian species, the cobra and Russell's viper, have no amylolytic action, but a lecithinase action which was at first diminished, then augmented, and finally attenuated on heating progressively from 50° to 100° C. Cobra venom has some slight action on olive oil, and curdles milk and liquefies gelatin very feebly. The venom of Russell's viper also curdles milk feebly. Strong doses of cobra venom favour heat-clot of normal horse-serum, and watery solutions of horse-serum and of the red corpuscles of the horse are precipitated by concentrated solutions of cobra venom. As regards the specific action of venoms upon the blood, of the 17 venoms tested 11 are described as coagulant and 6 as anticoagulant. Experiments in vitro show that the phase of coagulation influenced varies widely; for example, the proteolytic venoms act on fibrinogen and may render it incoagulable, while others impede the

alteration of thrombin. The special phenomena of coagulant venoms in vitro, the effects of different physical and chemical conditions in modifying those phenomena, and the interaction of toxin and antitoxin have also been studied. The times of clotting have not been found to vary parallel with the quantities of venom. Excessive doses of these coagulant venoms prevent clotting by altering the fibrinogen, and it is thus necessary to experiment with progressive doses of venom. Salts, particularly oxalates, impede the clotting, as also does peptone. Mammalian plasma is more easily clotted than that of birds, reptiles, and batrachia. The clotting constituents of the venoms are filtered with difficulty, do not dialyse, resist alcohol, are precipitated by ammonium sulphate, and destroyed by potassium permanganate. Progressive heat either gradually diminishes the power of the venoms, or, more often, causes a sudden and marked diminution followed by recuperation. Antitoxic plasmas and serums are highly but not rigidly specific. There is not, so far as can be seen, any oppugnant principle between anticoagulant and coagulant venoms; the difference between them depends upon the action of the anticoagulant venoms upon fibrinogen. Experiments in vivo, most successful on the dog, show that in coagulant venoms the clotting is directly due to precipitation of fibrinogen by the venom itself. This "positive phase" is succeeded by a "negative phase" in which, as a consequence of the complete precipitation of fibrinogen, and not because of any formation of antithrombin, the blood is incoagulable. The anticoagulant venoms must be injected in large doses to produce their characteristic effect, which is due, not to precipitation of fibrinogen—though fibrinogen is diminished—nor to any formation of antithrombin, but to direct destruction of thrombin.

MIKULICZ'S DISEASE.

WE published in THE LANCET of Sept. 4th a note by Dr. S. G. Askey on this rare condition, and on Sept. 11th a letter from Dr. Dan Mackenzie describing several cases of his own. We now draw attention to a very remarkable and interesting example of the same disease communicated¹ by Professor Nino Samaja which occurred in the Ospedale Maggiore. His case is of exceptional interest not only because all the salivary glands which are clinically observable were affected by the same morbid process, but also because the enormous increase in volume of the pharyngeal glands on the right side produced an occlusion of the Eustachian tube with unilateral deafness. Professor Samaja states that none of the throat and nose specialists to whom he referred the case had ever met with unilateral auditory disturbance due to this cause, associated with symmetrical hypertrophy of the salivary and lacrimal glands.

The patient was a man, 62 years of age, who had been extremely healthy until he began to experience tinnitus and deafness in the right ear. When he came under observation there was marked hypertrophy of the lacrimal, parotid, and submaxillary glands. On raising the tongue the two enlarged sublingual glands were seen, while the apical glands of Blandin-Nuhn could be palpated, and the palatine glands were visible when the mouth was widely opened. By palpation various other glands were felt to be enlarged, notably the epitrochlear, cervical, axillary, and inguinal (in the latter situation they were as large as a pigeon's egg), rather hard, not tender, and adherent neither to the skin nor subcutaneous tissue. Saliva was somewhat scanty, but other organs presented no abnormalities. Examination of the eyes showed bilateral pterygium and papillary hypertrophy of the conjunctivæ; the lacrimal ducts were pervious. Posterior rhinoscopy revealed that the rhino-pharyngeal space on the right side was occupied by a fleshy mass, pale pink in colour and of smooth contour. Wassermann's reaction was negative, and the blood count showed the relation between white and red cells to be 1 to 941, lymphocytes 26.5 per cent., large mononuclears 3.5 per cent., polynuclears 66 per cent., eosinophiles 1 per cent.—an almost normal proportion.

In Professor Samaja's case radiotherapy was followed by brilliant results: six applications were given with an aluminium filter of 3 mm., spark equivalent 25,

¹ *Bullettino delle scienze mediche*. 1920. Via Altabella 6, Bologna.

milliamperes $\frac{1}{2}$, duration 20 minutes. Forty days after the last application most of the enlarged glands had disappeared and also the deafness and tinnitus. The effect on the blood count was that the relation between the white and red cells increased to 1 to 604, while at the same time a marked eosinophilia was produced. Professor Samaja distinguishes clinically pure forms of Mikulicz's disease (hypertrophy of the lacrymal and salivary glands without concomitant lesions of other systems) and forms associated either with general lesions of the lymphatic system (leukæmia, pseudo-leukæmia, lymphosarcomatosis, &c.) or with general infections, and he states that the prognosis is in direct relation to the general disease with which Mikulicz's syndrome is associated.

DISLOCATION OF THE CARPAL SCAPHOID.

In the *Boston Medical and Surgical Journal* for August 26th Dr. William Pearce Coues has described a very rare injury. Dislocation of the carpal scaphoid alone, or associated with semilunar dislocation or fracture, is one of the rarest of injuries. Scaphoid dislocation, when it does occur, is usually the result of a fall from a height on the hyperextended hand. If the radius does not give way the force of the impact is transmitted to the os magnum through the dorsal corner of the semilunar, which brings pressure on the neck of the scaphoid, while the anterior part of the capsule fixes the bone at the centre. Ordinarily from this force a fracture through the neck of the scaphoid results.

A carpenter, aged 54 years, was examined for the Massachusetts Industrial Accident Board on April 7th, 1919. On Jan. 20th, while descending a ladder, he slipped and fell some 20 feet on a concrete floor. He was unconscious for some time after the accident, and was treated in hospital for three weeks. On examination a depressed fracture of the frontal bone and of the head of the right radius, with much new bone about the elbow-joint and practically no motion, were found. There was also inability to use the left wrist, with aching, stiffness, and general disability of the hand. Examination showed bony thickening about the wrist and the styloids practically on a level. There were only a few degrees of active motion at the wrist-joint in any direction, and attempts to increase this passively caused pain. The thumb and fingers were stiff, but he was just able to oppose the thumb to the index finger, although he could not flex the fingers into the palm. The grasp of the hand was weak, and rotation of the radius was restricted. On the palmar aspect of the wrist, just below the end of the radius, was a marked bony prominence. This was immovable and seemed to block the wrist motions almost completely. It corresponded in general level to the situation of the scaphoid. Radiography showed the lower end of the radius fractured and complete dislocation of the scaphoid, with some displacement of the semilunar. It seemed that operation would give the only chance of a useful wrist, but on account of the condition of the other arm the patient declined.

In connexion with this and allied injuries the experiments of Honigschmied are of interest. In 19 cadavers he forcibly extended the hand. In 17 fracture of the lower end of the radius resulted and in 2 rupture of the anterior ligament of the wrist with anterior dislocation of the semilunar. In 8 cases a preliminary dissection of the wrist was made before hyperextension. In 5 the palmar capsule was lacerated, and twice the scaphoid was partially dislocated, and once the ligament between the two rows of carpal bones was torn. It would seem that in the case of scaphoid dislocation from hyperextension intercarpal ligamentous rupture with lateral torsion of the wrist would best account for this unusual injury. The bone is probably suddenly squeezed out of its bed as one shoots the stone from a cherry, a mechanism graphically described by Eigenbrodt in explaining dislocation of the semilunar bone.

THE Harveian Oration will be delivered at the Royal College of Physicians of London by Sir Frederick Andrews at 4 P.M. on Monday, Oct. 18th.

THE Italian Government have conferred the Italian silver medal *Al Benemeriti della Salute Pubblica* upon Dr. Leonard Hill, F.R.S.

PUBLIC HEALTH IN SOVIET RUSSIA.

By L. HADEN GUEST, M.C., M.R.C.S. ENG., L.C.C.,
SECRETARY AND PHYSICIAN TO THE BRITISH LABOUR DELEGATION.

IV.—GENERAL AND SOCIAL DISEASES.

THE difficulty of forming an accurate impression of health conditions in Soviet Russia is much increased beyond that usual in all countries by (1) absence of trustworthy statistics; (2) great variation in conditions from one part of Russia and Siberia to another; (3) disturbances due to revolution and to war.

Malnutrition and its Results.

With regard to general nutrition it has been already pointed out that the towns are half-starving. The industrial workers are many of them anæmic, underfed, some obviously very ill. But in the country districts conditions are better, and, speaking broadly, the peasants have enough to eat, although they may lack certain things, such as salt (Samara Province) or meat (in most provinces). Dr. Semasko described one province to us—that of Nijni-Novgorod—as a "starving province." But in Samara Province there was an abundance of eggs and milk—milk, in fact, was used for washing the hair in place of soap in a village visited by one of our number.

But I did not find it possible to get reliable statistics of births, deaths, and causes of death. It was said in Petrograd that the birth-rate was rising rapidly; on the whole, however, the birth-rate seems to be exceeded by the death-rate. Dr. Semasko stated that the birth-rate was going up, but had not reached the pre-war level. Infantile mortality is certainly high. The aged, too, have suffered severely, and the age at death is falling owing to the severity of the conditions of life.

Diseases of children have not markedly increased, but children are below their proper level of development. Rickets was estimated at 80 per cent. of the child population, but I did not see the severe types of case which were common in Vienna in 1919.

Scurvy has doubled its large pre-war figure, and I saw many cases in hospital at Saratov. I was told at Astrakhan that there were 642 cases in hospital then (June 7th), and that 900 cases had been evacuated to Saratov in May, 1920. There has also been a great increase in cases of night-blindness (attributed to shortage of fat), and a great increase in anæmia showing itself in women in a marked diminution of menstruation. *Tuberculosis* has increased very much in the towns, but not apparently more than in Central Europe generally. The Soviet authorities are attempting to increase the hospital accommodation and also the number of the tuberculosis dispensaries, and claimed to have large numbers of beds available. An actual instance at Astrakhan, however, shows the fallacy of mere paper plans and figures. At this place a new Soviet hospital for 750 infectious cases was "decreed." A hospital was brought into being, but it contained only 70 beds and was not properly equipped. It is claimed that since the Soviet Government assumed power there has been an increase of 40 per cent. of permanent beds available for civilians (excluding infectious cases). One of these newly established hospitals, installed in the palace of the ex-Governor at Saratov, was inspected; it was crowded and badly equipped, and although in a splendid building, produced an effect of dirt, deprivation, and poverty. The work of all these hospitals goes on under great difficulties owing to the absence of dressings, drugs, linen, and even of the necessary food. The milk required for hospital cases cannot be obtained in sufficient quantity, practically nothing in the way of an "invalid dietary" exists, while ordinary food, including black bread, is short.

Health of School Children.

No definite statistics are available with regard to the health of school children, as there is no system of medical inspection as in this country. From my own observations I should judge the conditions of school

THE MEMBERS OF THE BRITISH LABOUR DELEGATION TO RUSSIA.

From left to right (standing): Dr. Haden Guest (secretary of the delegation); Mr. A. A. Purcell (Woodworkers); Mr. Robert Williams (Transport Workers); Mr. C. R. Buxton (interpreter and secretary); Mr. H. Skinner (Printers).

children to be much on a par with those existing in the poorer parts of England, with a very great increase in the number of cases suffering from vermin and an increase in certain other ways, noticeably in tuberculosis and in some places of syphilis. A number of institutions for treatment of children have been started in the towns and scattered in the provinces, including special sanatoriums for tubercular and pre-tubercular children and dental clinics. Dr. Semasko told me that children were being born weak, were developing badly, and had much tuberculosis and rickets. Also that the proportion of stillbirths had increased.

Syphilis and Preventive Measures.

Syphilis was stated to be very extensively distributed in Russia. Prostitution, of the old type at any rate, is rapidly dying out and the old prostitutes are being taught to work, but there is still very much venereal disease. Some figures were given me for Petrograd, Olonetz, and Novgorodski Governments for the years 1911-15, as follows:—Cases per 10,000 of the population: Petrograd, 156.1; Olonetz, 123.3; Novgorodski, 92.4. When I quoted a statement made by a Red Cross representative in Switzerland to the effect that 80 per cent. of the population of certain Southern Russian and Ukrainian villages were infected with syphilis, Dr. Semasko agreed that this was a reasonable estimate. As there is a practical absence of any drugs for treating the disease, the spread of syphilis is presumably going on at a rapid rate. The Soviet Government state that between January, 1919, and May, 1920, they opened 3363 beds for syphilis, with 29 special out-patient clinics and 11 laboratories for carrying out Wassermann reaction. I inspected one of the out-patient clinics in

Moscow. It was a newly established, practically unused place, with an adequate supply of instruments and furniture and a small supply of salvarsan and allied preparations. In addition to this treatment work the Bolsheviks carry out a propaganda by poster and by leaflet of a convincingly frank description. In Moscow I went over a sanitary exhibition in which were new models of men and women affected with syphilis, the rashes and sores being very well shown. A doctor was on duty in the exhibition to show people round, but there was only one person besides myself going the rounds when I was there. The models were very good, and horrible enough to scare anyone into a very reflective state of mind.

Alcohol Scanty.

It is well known that during the war the Czar prohibited the distribution of alcohol. The Bolsheviks, on taking over power from the Kerensky Government, have maintained this prohibition. Alcohol is said to be more disastrous in its effects on Russians than on Western Europeans. Very strenuous measures are taken against the use of alcohol. In the railway service, for instance, an employee who obtains alcohol illicitly and gets drunk is shot "without mercy," as the high officer who was my informant told me. At the time of the Bolshevik revolution very large quantities of alcohol were deliberately destroyed by the Bolsheviks, an officer who superintended this at one place telling me how he stood over the men doing the work with a revolver in his hand and tested each man on his leaving work by smelling his breath. A certain amount of alcohol is still in the country and can be obtained for medical purposes or by the especially privileged. I was

able to get six bottles of champagne, one bottle of old brandy, and three bottles of red Caucasian wine for use of sick. Other small quantities of alcohol were get-at-able in other ways, but generally speaking it is a matter of great difficulty to get wine or any kind of alcohol in Russia. And no doubt the absence of alcohol makes it easier for the Government to control the population. Now, however, the peasants are beginning to want a little wine.

As an example of the difficulties in the way of observation caused by the political disturbances may be mentioned the case of the Ukraine. It appears that ordered Government in that country simply does not exist over large areas. The Government recognised in one town may be repudiated in another only a few miles distant. Much of the country is under the control neither of the "Red" forces nor of their "White" antagonists, but of the "Greens," who are frequently mere plundering bands wielding the authority of bandit chieftains over big areas. There have been in the Ukraine since the revolution at least 16 different Governments. The conditions in that country are not better as regards infections (including syphilis) than Russia, but there is some evidence that considerable areas are more prosperous as regards the food of their own populations.

Reduction of Vitality.

What does emerge from this general survey of conditions is the universal distribution of dangerous infections, the lack of medical supplies, and in particular of soap and disinfectants, and the generally reduced vitality of the population, more especially of the town population. Civilised life is falling to pieces in Russia; the towns are more stricken than the country, and while power is in the hands of a small group of people in the towns, the support of this power is, in fact, very largely in the country population, who supply the armies and who feed the whole population. The danger that these conditions may lead to mere anarchy is obvious, and the existence of many millions of men and women infected with the most dangerous diseases known to exist in immediate proximity to Western Europe is a nightmare conception which should stir Europe to help Russia, even if motives of mere humanity do not.

There is no question of imposing another Government on Russia from without. That is a futile delusion of incompetent interventionists like Denikin and Kolchak. The decay of a whole civilisation must be arrested by many measures of help and assistance, which it is beyond the scope of these articles to deal with, but one of the most important is the provision of such medical assistance as shall give the Russian doctors the necessary drugs, soap, and disinfectants they need not only to save their own people, but to preserve Europe from the danger of virulent, widespread, and recurring epidemics of disease.

THE COLONIAL MEDICAL SERVICES: REPORT OF THE DEPARTMENTAL COMMITTEE.

BRIEF reference was made in THE LANCET of Sept. 18th (p. 626) to the Report of the Departmental Committee appointed to inquire into the Colonial Medical Services.¹ The terms of reference were as follows:—

1. To consider generally the position of the medical service of the various colonies and dependencies for which the personnel is now provided by the Secretary of State, with a view to maintaining and increasing the supply of candidates for appointment as medical officer and to securing contentment within the service.

2. To consider whether the principle of assimilating the medical service in neighbouring colonies, as already adopted in West Africa, may usefully be extended, and, if so, how far and by what means.

The Committee decided to hear evidence from witnesses competent to express the views of the

¹ Colonial Office: Report of the Departmental Committee to inquire into the Colonial Medical Services. Together with a letter from the Colonial Office to the Chairman of the Committee. London: His Majesty's Stationery Office, 1920.

medical staffs of the various groups of colonies to which appointments are made by the Secretary of State, and also from others acquainted with the conditions of the Colonial Medical Services.

A Unified Service.

In the opinion of the Committee the ideal is a unified service, the personnel of which would be recruited from men who had recently become qualified to practise and would be liable for service in any of the various colonies to which appointments are made by the Secretary of State. They realise, however, that the full attainment of this ideal is not possible at present, and in the various recommendations which they have made in this report they have kept this fact constantly in view and have confined themselves to such measures as are practicable, and would yet go far to meet the legitimate desires and grievances of the various services.

The Report sets out briefly the difficulties which appear to stand in the way of recommending the creation under present conditions of a unified service. These may be summarised as follows:—

(a) Members of a unified service must be servants of one Government and paid from the Imperial Treasury, while each colony is a separate Government paying its own medical officers with funds usually derived from local taxation.

(b) In some colonies the selection of candidates is made by the Secretary of State, whereas in others only the senior officers are so appointed, the junior officers being recruited locally and appointed by the Governor.

(c) There is a wide divergence between the salaries paid on first appointment in the various colonies.

(d) Racial difficulties obtain in some colonies to a greater extent than in others.

(e) The regulations as to private practice and the opportunities for such practice differ very widely.

(f) In most services the appointments are pensionable, but in a few they are not. Moreover, pension scales are not uniform.

(g) The regulations as to leave and passage differ widely in the various colonies.

(h) In many colonies knowledge of one or more local languages is very desirable.

If the recommendations of the Committee should be carried into effect they are of opinion that after a period of, say, five years, the experience gained should be reviewed by another Committee, in order that, if justified, further steps may be taken towards the formation of a still more unified service.

The Unification of the Colonial Medical Services.

Hitherto a candidate has applied for a medical appointment in a special colony or group of colonies. The Committee recommend that in future the application should be made for admission to "The Colonial Medical Service." The Report states briefly the nature of the following advantages likely to attend the creation of a unified Colonial Medical Service:—

(a) It would constitute a recognition of the Colonial Medical Service as a distinct branch of the public medical service of the Empire.

(b) The status of the Service in the opinion of the medical profession would be enhanced.

(c) The young medical man when asked, as he often is, "What are you going in for?" would be provided with a brief reply, carrying a definite meaning—viz., "The Colonial Medical Service."

(d) The above considerations would tend to encourage recruiting.

(e) Questions at issue affecting the interests of a unit of the Colonial Medical Service would be settled with much less display of feeling if those concerned knew that they had been submitted to a man of standing in their own profession.

(f) Possibly the most immediate and obvious advantage would be that throughout the Service it would be regarded as an attempt to provide them "with an adequate channel through which to express any feelings of discontent which may arise at any time."

The Head of the Colonial Medical Service.

The Committee are of opinion that an officer of standing in the medical profession, whose opinion would have weight with the Secretary of State, and whose name would create confidence in the medical profession, should be appointed a member of the Colonial Office staff, with a title commensurate with the importance of his position. The majority of the Committee recommend that he should be given the title of Director-General of the Colonial Medical Service. His duties may be set out as follows:—

(a) Generally he should advise the Secretary of State and the permanent staff of the Colonial Office on all questions relating to the personnel of the Colonial Medical Service as distinct from questions of medical and sanitary theory and practice.

(b) He should be accessible to all officers of the Colonial Medical Service who might wish to see him when they are at home on leave.

(c) He should advise on all changes in the regulations and conditions of employment of medical officers.

(d) He should assist in the interviewing of candidates and of possible candidates for appointment in the Colonial Medical Service.

(e) He should be a member of the subcommittee on colonial medical appointments if the present method of entering the service is continued. If it is not, he should be a member of whatever committee may be appointed to interview candidates for medical appointments before their admission to any examination that it may be decided to hold.

(f) He should keep in touch with the medical schools in the United Kingdom.

(a) He should be a member of the Advisory Medical and Sanitary Committee for Tropical Africa when questions of promotion are under consideration by that Committee, and also of the Promotions Committee of the Colonial Office in connexion with the fitness of officers for transfer and promotion in other units of the Colonial Medical Service. For this purpose he would have access to the confidential reports on officers of the Colonial Medical Service.

(b) He should endeavour to keep in touch with the feeling of the Service and to bring the existence of causes of discontent to the notice of the Colonial Office.

(c) He should be concerned in the preparation of an annual revision of the Colonial Medical Service List, to which reference is made below.

(d) Should it be decided to adopt the examination system as the method of entry into the Colonial Medical Service, all proposals relating to such examination and its details and conditions generally should be arranged in consultation with him.

Nursing sisters.—No reference is made to the question of the recruitment of nursing sisters. Nursing sisters and nurses are recruited by the Overseas Nursing Association, and there is no reason to doubt that the present arrangement is satisfactory, having regard to the terms offered by the various Colonial Governments. It would probably be desirable that the officer in question should be associated with the Overseas Nursing Association; he might perhaps represent the Colonial Office on the Committee, or be associated with the member of the Colonial Office staff who now sits on the Committee.

Matters outside the scope of the Director-General.—The regulation of the discipline of individual members of the Service whilst serving under Colonial Governments would remain with the Governor and Principal Medical Officer of the colony concerned.

Personnel of the Service.

In the opinion of the Committee it is most desirable that in future the attempt should be made to attract to the Service the best type of young men fresh from the medical schools. Stress should be laid on the importance of recently qualified men being seconded for a resident appointment, such as house physician or house surgeon, preferably at the hospital where they have received their education in the practical subjects of their profession, and failing that, at some other hospital not attached to a medical school, but approved for the purpose by the Secretary of State. The adoption by the army authorities of this system has been successful, and is advantageous alike to the individual and to the Service of which he has become a member.

Method of admission to the Service.—The Committee have considered carefully the proposal that admission to the Service should in future be by competitive or qualifying examination in place of the present method of classification by the Medical Appointments Subcommittee, and have come to the conclusion that the former method presents distinct advantages if, as they have already suggested, the personnel is to be recruited from amongst the men who have recently passed through the schools.

The Committee find that while on several minor points the Colonial Medical Service might be made more attractive the chief and only really important cause of the difficulty in adequately filling vacancies, apart from the scarcity of medical men during the war, is that the improvements in salary and pension prospects in the different colonies have not kept pace with increased rates of emoluments in other classes of medical employment and in private practice or with the increased cost of living.

It might, in the opinion of the Committee, be an advantage if the heads of the medical departments of the public services—viz., the Navy, the Army, India, and the Royal Air Force—could agree to hold a single entrance examination, as is done by the Civil Service Commissioners for the various offices of the Civil Service. Should such an examination be instituted the Committee recommend that the Colonial Medical Service should fall into line with the other departments concerned. Candidates should be interviewed and approved before examination.

The number of medical appointments in the colonies with which the Secretary of State is concerned is about 600. Assuming that the principle of admission to the Service by examination is accepted it would, in the opinion of the Committee, be necessary for the Secretary of State to reserve the right of appointment by selection to certain posts of a special character for which the method of admission by examination is unsuited. This would also apply to admission to certain new departments of the Service, to which reference is made at a later stage of the Report.

Organisation of the Colonial Medical Service.

As a completely unified Service is not at present possible, it would be necessary for candidates to offer themselves for service in those colonies for which they were eligible according to the regulations then in force. The Colonial Office is at present organised in geographical departments, each dealing with the affairs of one or more colonies or groups of colonies. These departments are: (1) Ceylon and Mauritius; (2) Far Eastern; (3) Nigerian; (4) Gold Coast and Mediterranean; (5) East African; (6) Tanganyika and Somaliland;

(7) West Indian. The affairs of Fiji, the Western Pacific High Commission, and the South African Protectorates are dealt with by the Dominions Department.

The Committee recommend that the Colonial Medical Service should be organised in the same manner and that candidates should apply for admission to the Service in one or more of those departments.

Assimilation of the Medical Services in Neighbouring Colonies.

The Report discusses in some detail the possibility of forming into separate units the medical services of neighbouring colonies. The medical services of the West African Colonies have already been assimilated and formed into the West African Medical Staff. The Committee have carefully considered the conditions prevailing in the different groups of tropical colonies, and find that the only other medical services that can with advantage be assimilated are those of: (a) The Straits Settlements and the Federated and Unfederated Malay States; (b) the East African Protectorates and the Tanganyika Territory. The Committee understand that transfers freely take place among officers in group (a), and that such transfers involve no loss of leave or pension.

The assimilation of the medical staffs of the four West African Colonies has been a conspicuous success. The Committee strongly recommend that a similar staff be formed for the East African Administrations, and that, as far as possible, the conditions of service, pay, pension, and gratuity be assimilated to those existing in the West African Medical Staff so as to facilitate the ultimate combination of the two services into one medical staff for British Tropical Africa.

Inspectors of Medical Services for West and East Africa.

Emphasis has been laid by several of the witnesses who appeared before the Committee on the desirability of frequent and regular inspection of the individual stations and the Colonial Medical Service generally by some medical man of senior standing, in the interests, not only of the public, but of the medical officers themselves. The Committee regard as a matter of urgency the appointment of officers charged with these duties for West and East Africa, who might be styled "Inspectors of Medical Services," so long as it is understood that "medical" includes the duties now classed as "sanitary." Officers whose duty it is to inspect regularly, in one case the West African Colonies and in the other the East African Protectorates and the Tanganyika Territory, will find plenty of work to occupy them for some six or eight months in the year. For other parts of the empire a system of occasional visits as opportunity serves, or some local emergency demands, by medical men of authority on tropical questions, seems to be all that is required at present.

Pay, Pensions, and General Conditions.

The Committee remark that salaries are at present low and that the cost of living is increasing, and note the necessity for increased pay. They are of opinion that it will be necessary for the Colonial Medical Service to offer an initial salary of at least £600 per annum for whole-time appointments. In many cases in pre-war times the salaries were wholly inadequate. The increased cost of living presses with double hardship upon officers serving in tropical and sub-tropical colonies who have to maintain out of a fixed income, not only themselves, but also their wives and families in this country.

Pensions and scales of pension.—The Committee understand that the question of the age of voluntary retirement and of rates of pension is under consideration, and, in the circumstances, they refrain from making any specific recommendations, but venture to express the hope that the claims of the medical officers will be considered in a generous spirit.

Gratuity on retirement after nine years' service.—The Committee recommend that the gratuity now given to officers in the W.A.M.S. who desire to retire after nine years' service should be continued and increased to £1500, notwithstanding the fact that few men have availed themselves of it. They also recommend that the gratuity payable after 12 years' service should be increased to £1875, and that similar gratuities should be instituted in the E.A.M.S., or even made general throughout the Colonial Medical Service.

Leave and passage.—The Committee have received but few complaints that the leave granted by the regulations is inadequate in point of duration, but several that the sum allowed for the payment of the passage home does not cover the cost of the journey, particularly when it is necessary to change steamers and remain at intermediate places awaiting the arrival of another boat. Several witnesses have complained that they did not get the local leave of 14 days or more in each year to which they were entitled. From the point of view of health and efficiency, it has been shown that, under certain conditions, relaxation is a necessity for the worker and an economy to the employer. Hence, it would appear to follow that the colony in which the officer has been serving should be responsible for his pay whilst on leave, and that the period of leave earned should be on full pay. The Committee consider that the regulation as regards passages

in force in the Straits Settlements—viz., that an officer returning home on leave is granted a free passage both ways for himself and his wife, and children up to the number of two—is equitable and deserving of general or modified adoption. Officers transferred from one colony to another and returning home before taking up the new appointment should receive free passages for the complete journey, whatever may be the salary of the new appointment.

Provision for widows and orphans.—The Committee understand that a scheme on the lines of that of the West African Colonies and Protectorates for making provision for widows and orphans of officers serving in the East African Protectorates is under consideration. They have received evidence in favour of this proposal, and express the hope that it will be possible to go further in this direction so as to include such European officers as are not now entitled to contribute to any existing fund.

Study leave.—The necessity for study leave, if a medical officer serving in the colonies is to keep abreast of the advance in medical science, has been recognised for some years, but the rapid changes taking place at the present date, particularly in the methods employed for accurate diagnosis, render study leave more than ever necessary. If the period of service to be followed by study leave is to be fixed, the Committee are disposed to put it at five years, and the duration of such study at not less than three months. Every officer should, in their opinion, be required to undergo a second course at the end of a further period of five years, and if an examination is held at the termination of the course to present himself for it. They do not think it is advisable to require that he should in either case pass the examination, but in considering his claims for promotion the fact that he has or has not passed the examination should be taken into consideration. It may be pointed out that the facilities for graduate study in London have since the war been greatly increased. Study leave should be on full pay, and the fees should be paid by the Government.

Specialist appointments.—It is now possible in the army for a man to attain to the highest rank and pay whilst continuing to practise the branch of the profession to which he has devoted his life. The Committee are strongly impressed with the desirability of introducing this principle, wherever possible, into the Colonial Medical Service. The presence on the staff of the larger hospitals in the more important colonies of a very able physician, surgeon, and gynaecologist and of specialists in these departments which are everywhere recognised—not omitting the head of the clinical laboratory—is of advantage not only to the patients under their care but to the whole of the medical men whose practice brings them into contact with that hospital. It is not, indeed, an exaggeration to state that the standard of clinical work throughout a colony may be raised by the existence of such a hospital staff. The Committee recommend that specialist appointments should be created and given to officers of the Service who have shown capacity in some recognised branch of medical science or practice, and who desire to continue their particular work.

Promotion.—It has been suggested that the increase of pay by annual increment is an evil, as tending to remove any incentive to effort; but the Committee are not disposed to adopt that view, and no evidence has been brought before them showing that it has had such an effect in the medical services of the colonies.

Designations.—The majority of the Committee recommend that the Colonial Governments should be urged to adopt a nomenclature which would be general throughout the Colonial Medical Service. The head of the medical department in each colony would be called "The Director of Medical Services" (D.M.S.). The next in rank, who would act for him in his absence, would be the "Deputy Director of Medical Services" (D.D.M.S.). According to the extent of the colony, the areas of administration, and the number of medical stations to be visited there would be one or more officers with the title of "Assistant Director of Medical Services" (A.D.M.S.). Then would come Senior Medical Officers (S.M.O.) and Medical Officers (M.O.).

Transfers.—The Committee are of opinion that, alike in the interest of the officers and of the Service, it is desirable to facilitate these interchanges, as they would tend to increase the attractions of the Service and bring into a colony new men with new ideas and a wider experience. They recommend that transfers should not be allowed to affect adversely the ultimate pensions of the officers transferred.

Housing.—The Committee have received a good deal of evidence showing that the housing conditions are very defective in many colonies, and that this is one of the causes of discontent. They recommend that the attention of the local Governments be called to this point.

Confidential reports.—Discontent has been expressed at the system hitherto in force under which the individual officer is not acquainted with the nature of the reports on himself. The Committee understand, however, that it has recently been decided to introduce important modifications into this system, which they believe should go far to remove the objections felt by officers.

Posting to stations.—It is very desirable that a medical officer, on his arrival for the first tour of duty in any colony, should serve for at least a month at the headquarters of the colony, and be attached for duty to the chief hospital, and at the same time learn the routine of administration.

Reference libraries.—The Committee recommend the provision of at least one medical reference library in each colony, and that a paragraph dealing with such libraries should always be included in the annual medical report of each colony.

Auxiliary medical service.—The evidence given leads the Committee to the conclusion that there is room in the West African Colonies for an auxiliary medical service on the lines of that of India or Ceylon. Before such a service could be created it would be necessary to found a medical school. As such a scheme would take some years to mature—i.e., before the first native obtained the licence of the college to practise—it should, if approved, be taken in hand as early as possible. Assuming that the personal material exists from which such a staff could be recruited, it would go some way towards meeting the legitimate desire of the natives to obtain a larger share in the civil service of their country.

Research.—There is no better investment for the money of any colony than scientific research, both medical and economic, and the Committee recommend the creation of such a department as part of the Colonial Medical Service. Any medical officer who may show a capacity for research work should receive every possible encouragement, and such officers in charge of clinical laboratories as give evidence of such capacity should be promoted to the research service, but appointment by special selection should not be excluded. The Committee recommend that a Medical Research Institute under a director should be established in every important colony or group of colonies, and that wherever possible the institute should be placed near to the largest and best-equipped hospital, so that the two institutions may mutually influence each other's standard of work.

Precedence and honours.—In West Africa the heads of the medical departments have been placed on the executive councils, either *ex officio* or personally, and in view of the increasing importance attached to medical and health questions, especially in the tropics, the Committee would be glad to think that this change was likely to become general. The question of the grant of honours by the Sovereign to the medical departments is a more delicate matter, and one on which the Committee hesitate to offer an opinion. They notice, however, that only three present members of the Colonial Medical Services have been the recipients of the C.M.G. for services rendered under the Colonial Office.

The Colonial Medical Service List.—The Committee were impressed with the fact that in the past the existence of the Colonial Medical Service has been almost unknown to the bulk of the medical profession. They state that in their opinion there should be, in addition to the institution of an entrance examination, a Colonial Medical Service List, giving full information as to the conditions of service under the various Colonial Governments and the names, qualifications, and services of the officers in each unit of the Colonial Medical Service. The names and services of the locally appointed officers should also appear in this list.

In conclusion, the Committee express their belief that by the adoption of their recommendations the causes of discontent which have existed in the Service in the past will be removed, and that the Colonial Medical Service will attain to a very high, possibly even to the highest, status amongst the public medical services of the empire.

Progress Already Claimed.

An appendix contains the names of those who gave oral evidence before the Committee. There is also appended a letter from the Colonial Office to the chairman of the Committee, in which considerable progress is claimed in the direction desired by the Committee. These instances are cited:—

1. The unification of the East African Medical Services has already been accomplished in everything but name, as uniform scales of pay have been introduced in all the administrations concerned, and there are uniform regulations as to pension, leave, &c., while the principle of promotion from one Dependency to another in East Africa is recognised.
2. The salaries of the West African Medical Staff have been completely revised, and an initial salary has been adopted in excess of the minimum of £600 a year recommended by the Committee.
3. Considerable progress is being made in the improvement of facilities for research in the colonies: in the case of the Gold Coast, for example, provision is being made for the creation of a special research department, with a staff consisting of a director and six pathologists.

The Report is signed by the following, who constituted the Committee: Sir Walter Egerton, K.C.M.G. (chairman); Sir Harry Verney, Bart., D.S.O.; Sir Humphry D. Rolleston, K.C.B., M.D., F.R.C.P.; Major-General Sir W. B. Leishman, K.C.M.G., C.B., M.B., F.R.C.P.; Lieut.-Colonel Sir James K. Fowler, K.C.V.O., C.M.G., M.D.; Mr. T. Hood, C.M.G., M.R.C.S., L.R.C.P.; Mr. A. Fiddian; with Mr. J. E. W. Flood as secretary.

HYGIENE ON THE SEA: ACCOMMODATION FOR SEAMEN IN SHIPS OF TO-DAY.¹

(BY OUR SPECIAL CORRESPONDENT.)

II. THE "OLYMPIC."

THE *Olympic*, of the White Star Line, had an honourable history in the war. She went at great risk to help H.M.S. *Audacious* when that ship was mined; she carried myriads of United States troops to Europe; she ran down and sank a German submarine; and she is the biggest ship built in England, so it was with very particular interest the other day, at Southampton, one went aboard her, reconditioned as she is and sumptuously equipped to make the week's voyage across the Atlantic as free as possible from the traditional hardships of the sea.

Board and Lodging.

Her numerous decks have such lengths of stairs and passage ways that one can easily lose oneself, and in fact I was on board her for hours and saw most of her accommodation, "fore, aft, and amidships," but never found her gymnasium, Turkish bath, swimming bath, or full-sized racquet court, enormous though the space must be which such equipments absorb. The *Olympic* herself is 46,359 tons gross, 22,350 tons register. She is 882 ft. long, 92½ ft. wide, and her load draught is 34·7 ft. Her 50,000 horse-power engines, working on four screws, drive her at 22 knots. When she goes to sea she has generally 3000 people on board; there are boats for 2600 and rafts for the remainder. She carries some 950 first-, 780 second-, and 1100 third-class passengers, with 800 of a crew to look after them, feed them, and keep them safe. The personnel of the chief steward's division is the most numerous, in all 564, amongst whom are the saloon and bedroom stewards and stewardesses; the chef, the chief baker, and the chief butcher and their associates, 90 of them, the staffs for the Turkish bath (male and female), gymnasium, and racquet court, and the barbers. The engine-room has a staff of 165 men now the ship is burning oil, and there are 89 sailors of various ranks and duties. Dr. J. C. H. Beaumont, the medical officer of the ship, and his associate, Dr. Robley Browne, had been instructed by Mr. Curry, the local manager, to show me round the ship of which they are naturally proud, and they kindly gave me every information. To them this account owes most of its interest. Before we get to business I may say that the sumptuous decoration of the best suite, that in which Miss Mary Pickford had just travelled, with its luxurious furniture and richly carved decorations, reminded me of nothing I had ever seen before in a ship; only in the Kaiser's dining-room at the Kiel Yacht Club, a room built ashore to simulate a cabin in a ship, could I recall a parallel.

Sanitation on board a ship is mainly a question of water, food, and air. Drinking water is here very carefully supervised. As it comes from the shore it is stored in well-cleaned cemented tanks, from which it is pumped to large receivers, whence it passes through Chamberland filters before it is distributed, sterilised, to the many small ice-filters all over the ship. Domestic water-tanks for washing water are cleaned and refilled each half voyage. The daily expenditure of water is about 250 tons.

Food on board these liners is so well cooked and so generously provided that it gives the hygienist no anxiety. The daily quantities used are expressed in large figures: meat, 4000 lb.; bread, 3000 lb.; fresh vegetables, 2500 lb.; poultry and fish, of each 2000 lb.; bacon, 1500 lb.; butter, 500 lb.; eggs, 6000; and potatoes, 3 tons. There are four kitchens, one for each first-class saloon (here the second-class meals, too,

are cooked), another for the third-class, and a fourth for the crew. There are also separate bakeries. Milk is carried in special refrigerators, and there are separate cool chambers for meat, fish, butter, cheese, eggs, vegetables, and fruit, also for fruit and flowers brought on board by passengers.

Rival Ventilation Systems.

Ventilation is the crucial hygienic question in a ship. The builders of the *Olympic* did a very wise thing when to the three funnels the engine-room required they added a fourth as a ventilating uptake. A ship with her great hot engines necessarily overheats all the air within her, and that air will, of course, escape if a path is open to it, usually by cowls or hatches. Generally there are not enough of these openings, for in bad weather they would all let rain in and that might be even more unpleasant than bad ventilation. Here is the wisdom of a funnel for ventilation; the up-draught is always so strong that the descending rain is carried back, the draught is strong (the funnel rises 60 ft. above the deck), and the volume of air carried out of the ship is enormous. There are side ports in some cabins, through which some air is supplied. But there are inside cabins without ports, and there are the public rooms, as well as passages and sanitary annexes. These are all ventilated by a double system of supply and exhaust ventilating trunks. Fifty large fans force air into every part of the ship, taking their supply from eight thermo-tanks, which in cool or in cold weather warm the entering air to any temperature desired. Twenty-four suction fans are always taking the heated and used-up air out of the ship and discharging it up the ventilating funnel. In addition, each stateroom has an electric fan for hot weather and an electric radiator for winter, so comfort is well considered. In the old days, when the merits of plenum and vacuum systems were being discussed, I felt that, as the old saying has it, "baith's best," and I was pleased to find such good results from them here. So far as one could judge in harbour, and as regards the decks on which people live, the *Olympic* is an unusually well-ventilated ship. It is said on board that as a result there is never any smell of cooking, and that smoke does not remain in the large smoking rooms, both severe tests. Oil-burning also helps ventilation. There is now no coaling and no coal-dust to dread, so the ship is no longer hermetically sealed up for most of her time in harbour, but can be left open to air herself all the time she is not running.

Lavatories and Conveniences.

The first-class cabins have fixed basins and hot and cold water laid on. So have the second class. Wealth will obtain for you increased comfort. In a larger cabin you may have a hanging cupboard for your clothes, you can add a private bath (hot, cold, and spray) and also a private sitting-room. The first-class division includes a dining-room for valets and ladies' maids which is a comfortable place. In the third-class each cabin has a folding wash-place with a water-tank filled by hand daily. There are 16 bath-rooms in this section, and the cabins are quite good, even if small. The general third-class accommodation includes saloon, social hall, smoking-room, and children's room, with the poop and well-deck for open-air exercise, so that advances in comfort are not made only for millionaires. It was in the *Oceanic* years ago I first saw hot ovens for warming the plates of third-class passengers. One great advantage of these newer ships is their complete freedom from insect pests.

The stewards have their accommodation amidships, arranged in small dormitories for about 20, for each man a comfortable bed and a locker. Their lavatories, water-closets, and bathrooms are well equipped. Forward on the port side there is a large mess-room for stewards, with a bar. Here they may have their meals, though often they are so pressed for time that they prefer to get their meals in the old bad way, standing in the pantry. But at night, when their work is done, they have this mess-room of theirs for a canteen and recreation room—a vast improvement on old-time conditions. I should imagine this improvement to be due in

¹The former article on Accommodation for Seamen in the *Aquitania* appeared in THE LANCET of Sept. 11th, p. 569. In that article the cubic dimensions of the cabin for two men should have been given as 648 (9×9×8) and not 728 cubic ft. 300 in the following line should read 220.

part to awakening conscience, but even more to the increasing size of ships, while the numbers of staff carried are not increasing quite so fast.

Seamen's Quarters.

The seamen, about 80, and engine-room staff (apart from officers) live forward in cabins very like those of the third-class passengers, but not all the beds are of that quality, for I saw several of the old "donkey's breakfast" pattern, beds stuffed with straw. Their cabins generally hold each three men, who can rarely be there together, and each has in it a basin. The seamen petty officers have a mess of their own, but the rank and file have their meals in a spacious mess-deck similar to that of the stewards, but over the other side of the ship, with fixed tables and forms for seats. The only place in the ship I did not like was the lavatory water-closet accommodation for "oil attendants." (I did not see the seamen's accommodation.) It was dingy. It had a yellow dado round it. I think everything else in the ship was painted white: a great thing, it costs money, but it shows up dirt and so increases health, and it raises the self-respect of the men. Whitewash is, of course, anathema, except perhaps overhead. The yellow dado gave one at once a suggestion of forlornness, discomfort, and neglect. The water-closet compartment was bounded by a considerable area of the ship's side. That had been painted with cork paint, but with very thin cork paint, not enough, in my opinion, to keep out the cold of English seas, let alone the winter temperature of New York. Surely those surfaces and the pipes there could be cased in wood, or at any rate have wooden shutters over them to keep the cold off. The water-closets were of the same order of comfort as the yellow dado. I think it was a trough closet, it was choked, the seats were wet and dirty and not scrubbed, there were no latrine-paper boxes, no latrine paper, and only a torn sheet of newspaper lying on the floor. There were lavatory basins with cold water only, and there were two douche-baths with hot and cold water. These last were the only fittings that gave any joy to an acquaintance I made at this point. He seemed to have nothing to do, and was very helpful—a fireman, he said, of the ship, and a Seamen's and Firemen's Union official, I gathered. I asked him to admire the accommodation for the men in this ship, but he would not. I asked him if he had ever seen better. He had, he said, in the German Merchant Service. It might have been; they were a good deal ahead of us before the war in looking after their crews. He complained of the water-closets, &c.—very reasonably, I thought. His tone was indignant and querulous, and I could not blame him. Seamen have found it hard to get their grievances redressed. Why not hot water to the men's wash-places? Their hands want a great deal of washing, even though the fireman of to-day, called now an oil attendant, talks of his work as a "gentleman's job," as it only takes sense, not physical toil, and involves no sweat and no dirt, and there is a hot-water supply close by.

Hospital Equipment and Nursing.

Dr. Beaumont showed me the very complete hospital equipment, a dispensary and operating-room, in which 89 anæsthetic operations were done in the three and a half years before the war. On no occasion was it necessary to stop or slow the ship, so steady is she. There is a hospital for men, a hospital for women, also a hospital for infectious diseases with a special uptake ventilation. There is also a very good padded cell. The whole is lavishly equipped. There are an incubator for dealing with suspected throat swabs, &c., a dental chair, and a gas apparatus. There are electric baths and an ultra-violet-ray bath. I noted that the bedside receptacles for seasick persons are fitted with papier maché containers which, when used, are burnt. There is a dispenser, who has with him a mate, the ship carries two certificated nurses, and there are two medical officers, as I have said. The medical examination of the steerage passengers is an anxiety. It must be very exactly done this side and repeated on the voyage, or there will be trouble with the immigration authorities on the other side; but for the moment the

medical profession on board feels satisfied, as oil-burning has relieved the waiting-rooms of the formerly numerous cases of heat-stroke, colic, and wounds and abrasions of hands.

Before closing I must mention one of the many ingenious appliances on the bridge for facilitating navigation, the clear-view screen, allowing sights to be taken in rainy weather. The glass through which one regards the light whose position is wanted cannot be obscured by rain, snow, or fog as it is travelling round 1500 times a minute, and always comes up before your eye, warmed, dry, and transparent.

In conclusion I have to thank the company, and especially the local manager, Mr. Curry, for the particular courtesy with which they arranged that your representative should see everything thoroughly and comfortably, and also Dr. Beaumont, who got together for me so much of the detail which increases the interest of the above account.

MEDICAL EDUCATION IN AMERICA.

THE educational number of the *Journal of the American Medical Association* gives a moving picture of medical education in the United States. The facts, historical and actual, have been obtained by the courtesy of the authorities of the medical colleges in the United States, and are arranged in convenient tables which, when studied carefully, give clear pictures of the changes taking place. Of the 85 medical colleges now existing, 76 are described as non-sectarian, 5 as homœopathic, 1 as eclectic, and 3 as nondescript. A fifth class, the physio-medical, teaching a system of medicine from which all remedies are excluded except those derived from non-poisonous drugs, had 1 adherent college in 1850, 3 from 1902 to 1907, and is now extinct. The number of homœopathic colleges shows a steady descent from 22 in 1901 to 5 at present open. The eclectic schools show a similar decline, having numbered 10 in 1901. Eclecticism as it is known in America is a system of medicine which treats diseases by the application of single remedies to known pathological conditions, without reference to nosology, special attention being given to the development of indigenous plant remedies; an eclectic school is one which professes to select what is best from all other systems of medicine. The three so-called nondescript schools consist, in the words of the report, of two semi-osteopathic and one nominally eclectic affair. Two of them are not recognised even in their own State of Missouri and the third is in Massachusetts, which has a feeble medical practice law.

The total number (76) of non-sectarian medical schools has also steadily decreased from its maximum of 130 in 1906, but it is the more efficient colleges that have survived, and the proportion of students attending non-sectarian colleges has risen to 93·8 per cent. of the total number.

The Grading of Medical Schools.

Whereas in this country the choice of a medical school may safely be left to the individual student, who even if guided only by geographical position or a reputation for football cannot make a serious mistake, in America the standard of teaching and the value of the diploma when attained vary within wide limits. In fact, many of the diplomas given are recognised only in a few of the States. In order to protect the student from being enticed by misleading advertisements, and to raise the standard of medical education throughout the country, the Council of Medical Education and Hospitals of the American Medical Association has made extensive and repeated investigations of the training given at all the medical schools in the country and in Canada, and has rated them in three classes, A, B, and C, according to their degrees of excellence. The student is strongly advised to join a Class A medical school, where (as is shown by tables) the fees are as a rule no higher, and the length of course no longer, than in the poorly-equipped low-grade institutions.

Adequate instruction in the recognition, treatment, and prevention of diseases can be given only in acceptable (Class A) medical

schools, which have expert teachers, well-equipped laboratories, and dispensaries and hospitals where the student can study patients having all varieties of sickness and injuries.

Full details are given of the schedule on which the classification is based and of the standards required. The system of marking consists of establishing four general heads: (1) faculty, (2) product, (3) administration and supervision, (4) buildings and equipment, efficiency under each head being considered as of approximately equal importance, and being allowed 25 points.

Colleges obtaining 70 per cent. or above are rated in Class A, those obtaining from 50 to 70 per cent. in Class B, and those obtaining 50 per cent. or less in Class C. Class A colleges are those which are acceptable; Class B, those which, under their present organisation, give promise of being made acceptable by general improvements; and Class C those (a) which require a complete reorganisation to make them acceptable; (b) which do not keep satisfactory records of their students in regard to entrance requirements, attendance, grades in courses, division into classes, and reasons for promotion; (c) which do not enforce their requirements in regard to admission (including those admitted to advanced standing), promotion, and graduation; (d) which give the major portion of their instruction after 4 o'clock in the afternoon; (e) which are privately owned and conducted for profit; (f) which for other specific reasons are not eligible for inclusion in Class B.

The total number of Class A colleges in the United States is 70, including two homeopathic schools, all the rest being non-sectarian. It is satisfactory to note that 68 out of the 76 non-sectarian colleges (which, as we have seen, account for 93.8 per cent. of the total number of medical students) are acceptable, and that 89.6 per cent. of the total number of students are being educated at acceptable colleges.

The total number of medical students for the year ending June 30th, 1920, was 14,088, an increase of 1036 over last year; the number of students who graduated was 3047, an increase of 391 over 1919.

American Women in Medicine.

An interesting section of the statistics is that devoted to women in medicine.

During the past year there were 818 women studying medicine, or 132 more than last year, and 237 more than in 1918. The percentage of women to all medical students this year is 5.8, the largest percentage since the presenting of these statistics was begun. There were 134 women graduates this year, 27 more than last year, but 19 less than in 1917. Of all the women matriculants, 89 were in attendance at the one medical college for women, while 727 (90.1 per cent.) were matriculated in the 64 co-educational colleges. From the one women's college there were 12 graduates, while 122 (91.0 per cent.) secured their degrees from co-educational colleges.

This increase of women students in co-educational colleges is not surprising, since in recent years some of the largest and oldest medical schools, as Columbia, Tulane, the University of Pennsylvania, Harvard and Western Reserve University, have thrown open their doors to women.

Entrance Standards and Fees Payable.

The acceptable schools require a four years' high-school education or its equivalent, followed by two years' pre-medical college course consisting of chemistry, physics, biology, English composition and literature, and certain optional subjects, before admission. Among the directions laid down by the Council for the curriculum of an acceptable medical school are the following:—

The college should give two years of work consisting largely of laboratory work in well-equipped laboratories of anatomy, histology, embryology, physiology, physiologic chemistry, bacteriology, pathology, pharmacology, therapeutics, and clinical diagnosis. Present-day medical knowledge makes it essential that these subjects be in charge of full-time, well-trained teachers.

Two years of clinical work, largely in hospitals and dispensaries, with courses in medicine (including physical diagnosis, pediatrics, nervous and mental diseases), surgery (including surgical anatomy and operative surgery on the cadaver), obstetrics, gynecology, laryngology, rhinology, ophthalmology, otology, dermatology, hygiene, and medical jurisprudence. With the higher entrance requirements time is now available in the latter part of the second year for beginning courses in physical diagnosis and the principles of surgery.

It is the policy of the American Medical Association that as soon as conditions warrant, relations should be established with a number of approved hospitals so that a fifth undergraduate year may be spent by the student as an intern under the continued supervision of the medical school.

Post-graduate Experience and Training.

There are now 18 post-graduate schools in the United States, of which 7 are connected with universities in which the graduate teaching is, or will

be, as thoroughly and scientifically given as are the courses of the undergraduate medical school. The educational number does not deal largely with post-graduate work, but a list is given of 469 general hospitals throughout the country, which are considered in a position to furnish acceptable internships for medical graduates, followed by a list of 124 special hospitals. From the details supplied as to the number of beds, time and length of appointments, salary, and nature of experience to be obtained, the newly qualified man will get a fair idea of the kind of practical experience open to him.

The Cost of a Medical Examination.

The fees payable at the American medical schools vary within wide limits, and bear no relation to the grading. The majority charge between \$125 and \$225 a year for four years.

Although 45 colleges listed in Class A charge fees ranging from \$150 to \$350 per year for each student, the actual expense for teaching that student for the year in these colleges is much more than the fee charged. This larger expenditure is possible because the colleges receive either State aid or private endowment. This shows that no medical college can properly teach medicine on the income received from fees alone.

Taking the average at \$175 a year, or, disregarding variations in exchange, roughly £150 for the four years; the fees will be found about equivalent to those in this country, where the composition fee varies in the neighbourhood of £200 for a five years' course.

Recent Changes.

The changes for the better that have taken place during the last 16 years in medical education in the United States have been noteworthy, and are summed up in a leading article which we quote:—

In 1904, when the Council on Medical Education was created, the United States had more medical schools than all other countries of the world combined, the supply far exceeding the needs of the country. While the number of colleges has been reduced from 162 to 85 during the 16 years, the number enforcing an entrance requirement of two years or more of collegiate work increased from four (2.5 per cent. of all colleges) in 1904 to 78 (92.9) in 1920. The number of medical students was decreased from 28,142 to 13,052—the lowest number—in 1919; but, during the same period, the number who had higher preliminary qualifications was increased from 1761 (6.2 per cent. of all students) in 1904 to 13,408 (95.2 per cent.) in 1920. The number of graduates was reduced from 5747 to 2656—the lowest number—in 1919; but the number having higher preliminary qualifications was increased from 369 (6.4 per cent. of all graduates) in 1904 to 2842 (93.3 per cent.) in 1920. While the annual totals of colleges, students, and graduates have been decreased by about 50 per cent., the number of better colleges is 19 times larger than in 1904, and the numbers of better qualified students and graduates are nearly eight times larger.

Many other improvements have been made in the medical schools. Formerly, a number of them had no university connexion, were conducted for profit, or were dependent solely on students' fees. Most of them had inadequate buildings and laboratory space, inadequate clinical material, and their curriculums were only partly graded. Now all but a few are integral parts of high-grade universities; they are enjoying increased incomes, either from State appropriations or private endowments; many have erected new college buildings and installed more and better-equipped laboratories; they have employed larger numbers of full-time teachers. The majority of these schools are now carrying on more or less effective research; all have established closer relationships with hospitals furnishing clinical facilities, and the majority have adopted better methods of teaching in both laboratory and clinical departments. These changes, the report concludes, are producing physicians who, both educationally and professionally, are far better equipped to assume the responsibility for the prevention and cure of disease than those graduating in any former period.

UNIVERSITY OF MANCHESTER. — The Vice-Chancellor, in his annual report, just issued, points out the serious extent to which the University is being crippled, the want of adequate funds affecting staff, accommodation, and research. The none too successful appeal for £500,000 at the close of last year realised less than half the sum required; the appeal is, however, still before the public. Including the School of Technology, 2775 students attended during the session, compared with 1649 in the previous session and 1415 in 1914-15. The women students now number 572, and of these 143 are studying medicine.

TUBERCULOSIS.

The Report of the Ministry of Health.

THIS Report, the appearance of which was briefly noted in THE LANCET last week, includes a colourless, but no doubt accurate, review of recent measures for dealing with tuberculosis. It is a tale of committees, recommendations, grants, and schemes. It does not reflect favourably on the wisdom and prescience of the Departmental Committee on Tuberculosis that it should in 1912 have set the tentative standard of one sanatorium bed and one hospital bed per 5000 of the population, but though the insufficiency of this standard is now admitted, the 1 in 1000 standard, as already established in Denmark, has not apparently been accepted by the Ministry. There are, however, interesting facts to be extracted from this Report, serving, as milestones on a dull road, to mark progress. There are now 15,781 beds for the tuberculous under voluntary bodies and local authorities, and 2258 of these beds were provided during the year under review. Up to March, 1920, proposals had been submitted for the provision of 9830 additional beds. Thus it appears that the crying need for beds is rapidly being made good. The staffing of the tuberculosis machine is also beginning to come up to strength, or nearly so. By the end of March, 1920, county councils had appointed 150 tuberculosis officers, and county borough councils another 108. Tuberculosis dispensaries have also been staffed by 41 tuberculosis officers under the schemes of the metropolitan borough councils. Even the dental welfare of the tuberculous, which has in the past suffered much stepmotherly inattention, is coming to the fore, and by the end of March, 1920, arrangements by 15 county councils and 20 county boroughs for dental treatment of the tuberculous had been sanctioned by the Ministry. In so chronic and subterranean a disease as tuberculosis the latent period between any given measure and the effect it produces on the mortality must necessarily be long and uncertain. But it is encouraging, even if the declining tuberculosis mortality is only in part traced to the activities of the Ministry, to note that whereas the deaths in England and Wales from all forms of tuberculosis in 1918 were 58,073, in 1919 they were only 46,312.

The Tuberculosis Beds of the M.A.B.

If the number of beds provided for the tuberculous is an index to the efficiency of an anti-tuberculosis campaign, then the Metropolitan Asylums Board is to be congratulated on its annual report for 1919-20. As Appendix C shows, the Board's existing and prospective accommodation for the tuberculous is one of 2593 beds. It is not yet possible to judge whether the needs of London have been met by this accommodation, existing and prospective, but the report suggests that the supply will approximately meet the demand. One of the latest steps to be taken by the Board has been the acquisition of an institution at Lowestoft with accommodation for 150 cases of surgical tuberculosis in adults. In the section dealing with finance it is pointed out that the Government originally promised to defray three-fifths of the capital cost of sanatoriums up to £90 per bed. Though this sum was doubled in 1918 the amount is quite inadequate, for it is calculated that three-fifths of the capital cost per bed is likely to exceed £500.

Sanatorium Benefit in Kent.

In the seventh annual report on tuberculosis in Kent Dr. Alfred Greenwood edits the reports received from the seven tuberculosis officers in charge of various districts in the county. The interest of these sectional reports is enhanced by the divergence of opinion, not to say conflict of opinion, expressed by their authors. Some are dogmatic, others agnostic. Stressing the potency of domiciliary infection, one tuberculosis officer calculates that in his area nearly 7 per cent. of his cases of pulmonary disease occurred in "contacts." Hence his plea for the isolation of the advanced and hopeless cases.

Another tuberculosis officer writes:—

"Many of our old beliefs are being shaken, and even the very infectivity of tuberculosis, as we have up to now understood the term, is being questioned the cold truth remains that the medical profession is not yet in possession of the full requisite knowledge either as to the cause, prevention, or cure of tuberculosis."

The remedy is, in his opinion, research work. With regard to the conflicting claims of treatment at home or in a segregation camp, euphemistically termed an industrial colony, Dr. C. C. A. de Villiers, T.O. for district No. 6, advocates the establishment of workshops in each town or area, where men still undergoing treatment can be trained and employed while in receipt of their allowances.

"The training colonies are doing excellent work, but the large majority of men are either unable to comply with the conditions of admittance or are unwilling to leave their homes for any considerable period of time."

American Reports.

Trudeau Sanatorium (Thirty-fifth Annual Medical Report).—The reports published by this sanatorium are always stimulating as well as instructive, and Trudeau's successors show a happy combination of imagination, hustle, and perseverance. To combat the common tendency of sanatorium work to lapse into a rut of dull routine, all examinations and data found to be uninteresting are ruthlessly "scrapped," and new methods and points of view are constantly being studied. The X rays have been found to stimulate interest in the usual physical examination, and the Monday morning diagnostic clinics, where the entire staff meet to discuss individual cases, have proved a valuable whetstone on which to sharpen wits. Another prominent feature of the Trudeau Sanatorium is the close co-operation of clinical and laboratory work. Unfortunately, most sanatoriums provide few or no facilities for adequate research, although the problems of tuberculosis are obviously not going to be solved by the casual investigator. Among the papers published in conjunction with this report is one on the adrenalin test (Goetsch) between pulmonary tuberculosis and hyperthyroidism. It has been employed at the sanatorium for several years and has proved of considerable value.

Loomis Sanatorium, U.S.A. (Twenty-third Annual Report).—What, it may be asked, is the chief function of a sanatorium report? The authors of this report would be justified in calling it propaganda, for they have produced a beautifully illustrated work showing the attractions of the sanatorium surroundings in both summer and winter. Sandwiched in among these pretty pictures is much solid and useful information. Tuberculin, it appears, is given in only a few cases, whereas treatment by artificial pneumothorax is practised in about 19 per cent. of all the cases. The "gratifying success" achieved by this treatment is attributed to careful selection of cases and to the compression of the lung being gradual, except when severe hæmorrhage calls for rapid compression. Interesting studies have been carried out on patients suffering from hay fever, and their pollen sensitiveness was "skin-tested" in some cases with as many as six different pollen extracts. Practically all reacted to ragweed pollen. In addition to routine studies the sanatorium is undertaking: (a) an intensive statistical study of the previous year's work on complement fixation; (b) a study of the blood in acute cases of tuberculosis to determine the presence or absence of ferments; and (c) co-operation with the medical staff in a series of animal experiments on chemo-therapy in tuberculosis. It is evident from various other subjects discussed that Loomis Sanatorium is conducted on progressive and scientific lines.

LITERARY INTELLIGENCE.—Messrs. J. and A. Churchill announce a Text-book on Preventive Medicine, by Professor R. T. Hewlett and Dr. A. T. Nankivell, shortly to be published.—Messrs. Witherby and Co. announce that they will shortly publish a book entitled "A Naturalist in Himalaya," by Captain R. W. G. Hingston, M.C., I.M.S.

CONTROL OF VENEREAL DISEASE: RECENT CONTINENTAL MEASURES.

NORWAY.

Venereal Disease and Marriage.

RECENT legislation in Sweden dealing with venereal disease in relation to marriage¹ has its counterpart in Norway, and a comparison of the legislative reforms adopted in the two countries shows many parallel features. The Norwegian law, which came into force on Jan. 1st, 1919, does not deal at such length with venereal disease in its relation to marriage as the corresponding Swedish law, but as the following abstracts, for which we are indebted to the N.C.C.V.D., show, very important and far-reaching measures have been adopted to limit the spread of venereal disease, and to protect from infection the innocent party to the marriage contract.

Law of May 31st, 1918, Chapter I., §6.—A person infected with syphilis that is still infectious must not marry. The person who suffers from other venereal disease which is still infectious, or from epilepsy or leprosy, must not marry unless the other party to the contract is informed of the disease, and both parties have been given oral instruction by a doctor as to the dangers involved. The professional secrecy enjoined by the law on doctors does not apply to their disclosure, to the proper authority, of information intended to hinder a marriage being contracted contrary to the enactments of this paragraph. Doctors may be summoned as witnesses in matrimonial law-suits, and paragraph §178 of the criminal law does not apply to doctors in this connexion. The doctor who knows that the subject of any of the above diseases is taking steps to get married under this law is bound to communicate his knowledge to the proper authority.

Chapter II., §13, Nr. 5.—In connexion with the publication of the banns, each of the prospective parties to the marriage contract must give a written declaration to the effect that syphilis is not present in an infectious stage, and whether or not any other venereal disease still in an infectious stage or epilepsy or leprosy exists. If in the declaration the admission is made of the existence of a venereal disease other than syphilis, or of epilepsy or leprosy, proof must be given that the other party to the contract has been informed of this disease, and that both parties have been instructed by a doctor as to the dangers of the disease in question.

Chapter IV., §35, Nrs. 3 and 6.—In connexion with the annulment of marriage, this may be effected if one of the contracting parties has hidden from the other the fact that insanity existed before or at the time of marriage, or venereal disease still existed in an infectious stage, or epilepsy or leprosy, or an incurable physical deformity preventing sexual intercourse. The marriage may not be annulled unless this cause for annulment is pleaded within eight months of the date when the pleader was first informed of this cause.

Chapter V., §49.—A marriage may be annulled when one party can prove that the other party, knowing or suspecting that he or she suffered from venereal disease in an infectious stage, exposed the other party to infection by physical intercourse. If infection has not occurred, and if the disease is no longer infectious, the plea for annulment on these grounds cannot be made later than six months after the risk of infection has ceased. In this matter medical professional secrecy is ruled by the same conditions laid down in Chapter I., §6.

Instructions to Doctors Consulted about Venereal Disease.

In connexion with this law the Norwegian Medical Director has addressed a circular to all medical practitioners in Norway containing suggestions drawn up by the professor of dermatology in the University of Christiania.

Syphilis.—Owing to the capricious course run by syphilis, long periods of latency being interrupted by outbreaks of infectious symptoms, it has always been difficult to decide when a man or a woman who has contracted syphilis may marry with safety. Even the introduction of salvarsan and the combined salvarsan-mercury treatment and the diagnostic and prognostic assistance afforded by Wassermann's reaction have not made these problems easier. There is at present no reliable evidence as to the results of modern treatment, and such evidence is hard to obtain for lack of uniformity of treatment, not only in different countries, but in one and the same country. It can only be claimed that definitely better results are obtained than heretofore; but the disease is still apt to run an aberrant, uncontrolled course when least expected. It is, therefore, clear that the rules to be framed with regard to marriage must still be drawn up with severity and with an eye to the capriciousness of the disease.

A man or woman who has suffered from secondary syphilis must not marry till the expiration of two years after the completion of treatment, and he or she must during this interval have shown no clinical symptoms. The more vigorous the treatment the greater the confidence with which permission to marry can be given, but it is impossible to demand that treatment should be standardised; it should be regulated according to the needs of the individual case. As a rule, the patient should undergo several courses of treatment in the first two years after the outbreak of the disease. It is usual to insist on Wassermann's reaction being negative. It is, however, difficult to depend on this criterion, for there are cases in which

this reaction remains positive or soon passes from negative to positive in spite of treatment being vigorous. Yet in such cases there may be no further outbreak of the disease. It should also be noted that in several cases a positive reaction, which has been refractory to prolonged treatment, subsequently becomes negative for good. Tact and discretion are needed, and the decision should preferably be left to the medical man who has treated the patient and followed the course of the disease.

Should the disease break out afresh after the completion of treatment—a rare event if the treatment has been consistently carried out—thorough treatment should be instituted and permission to marry be withheld till the lapse of a one-and-a-half to two-year symptom-free interval and the demonstration of a negative Wassermann reaction. With regard to the woman, a new course of treatment should be recommended before she marries, however long a symptom-free period has passed. The object of this additional precaution in the case of women is the health of the progeny. Cases in which primary syphilis has been thoroughly treated and Wassermann's reaction has never been positive occupy a special position. Usually a complete cure is effected, and marriage may be permitted one to two years after the completion of treatment, provided there have been no clinical symptoms and Wassermann's reaction has remained negative throughout this period. As treatment in such cases takes only a few months, permission to marry may be given two to two and a half years after infection. But it is absolutely essential in these cases that the abortive treatment should have been carried out properly with a series of salvarsan injections, and that the case should have been under close medical supervision.

Code of Rules for Infected Persons.

With reference to Chapter I., §6, according to which the subject of venereal disease (other than syphilis) in an infectious stage and the subjects of epilepsy and leprosy must not marry unless the other party to the contract is cognisant of the disease and both parties have been given verbal instruction by a medical man as to the dangers incurred, the following suggestions and rules have been drawn up by the professors of dermatology and nervous diseases, and by the chief medical officer concerned with leprosy.

Gonorrhœa.—The prospective candidate for marriage, who has suffered from gonorrhœa, should be informed that many cases of acute gonorrhœa are not absolutely cured, but pass on to a chronic stage giving rise to such trifling symptoms that it may be completely overlooked. Yet such an apparently mild catarrh may sooner or later give rise to infection in the other party to the marriage. It is, however, a mistake to assume that every chronic catarrh following acute gonorrhœa is gonococcal. Indeed, most of these chronic catarrhs are not infectious. But it is very difficult to distinguish between gonorrhœal and non-gonorrhœal catarrhs, and the differential diagnosis should be made only by an expert. As chronic, as well as acute, gonorrhœa is far more frequent in men than women, medical men will be consulted chiefly by males, to whom it should be made clear that the transmission of the disease to women entails far-reaching consequences. Among these are sterility, which imposes mental as well as bodily deprivation. If the prospective candidate for marriage is a woman, suffering from chronic inflammation of the reproductive organs, suspected by her to be gonorrhœal, her medical adviser should first make sure of his diagnosis. This is a most difficult matter, requiring much time and careful examination; a single negative microscopic examination is of little significance. Many such examinations must be made at suitable intervals and only when a long series has proved negative can gonorrhœa be definitely excluded. Should gonorrhœa be diagnosed, the woman should be firmly dissuaded from marriage till she has undergone thorough treatment and has received her medical adviser's permission. Should she marry before she is cured she will not only infect her husband but she may also provoke an exacerbation of the disease in herself, rendering it incurable. Should her husband be cured after much suffering and prolonged treatment he may again contract the disease if his wife has not in the meantime been cured. In this manner gonorrhœa, which has evaded eradication at the time of marriage, may prove exceedingly difficult to stamp out.

Ulcus Molle.—Candidates for marriage who suffer from, or who have recently been under treatment for, this disease should be told that they may not marry till further propagation of the disease is impossible and assurance can be given that syphilis has not also been contracted at the same time as the chancroid. To be on the safe side this person should undergo Wassermann's test eight or nine weeks after infection. If this test is negative and there are no clinical symptoms it is permissible to assume the absence of syphilis.

With regard to Chapter II., §13, Nr. 5, it may be noted that when either of the prospective parties to marriage suffers from venereal disease, epilepsy, or leprosy the authorities celebrating the marriage must be assured that both parties have received instructions from a physician as to the dangers entailed. In this connexion a medical certificate is required. The law also refuses to recognise the privilege of professional secrecy in these matters; medical evidence may be called in litigation involving marriage, and a physician who knows that a person contemplating marriage suffers from any of the above diseases is bound to communicate his knowledge to the authorities concerned. In this connexion the medical profession is urgently reminded that contravention of the marriage law by persons suffering from one of the above diseases must not be facilitated by a conspiracy of silence on the part of the

¹ THE LANCET, 1919, vol. ii., p. 1164.

medical profession. In other words, active intervention is expected of the medical profession under certain conditions.

DENMARK.

Registration of the Syphilitic.

One of the movements in Denmark towards stamping out venereal disease which has aroused most discussion and criticism during the last two years is based on the principle of notification followed up by the registration and subsequent permanent supervision of every case of syphilis. More than one scheme has been outlined with this object in view, but its principal aims are kept in view by all concerned. The difficulties of such a universal centralised scheme are numerous and obvious, but Denmark offers exceptionally favourable opportunities for a comprehensive survey and control of all its syphilitic inhabitants, as its population is comparatively small and concealment and evasion are correspondingly difficult. Already one-half to two-thirds of all the cases of syphilis in Copenhagen are said to be under the care of State or municipal medical officers, and this material alone should form an admirable nucleus on which to build an elaborate system of research and treatment. It is proposed that every patient's dossier should be filled in a central office, where information as to his history, symptoms, reactions, and terms of treatment would be collected and analysed. By such a scheme, which would include periodic clinical and serological examinations, much would be learnt as to the development of tertiary phenomena, including disease of the central nervous system. The scheme would also enable pathologists to correlate their post-mortem findings with the patient's clinical and serological records. The cost of such a scheme would be negligible when viewed in the light of the financial burden already borne by the community in its treatment of general paralysis and other syphilitic diseases.

SWITZERLAND.

Compulsory or Voluntary Measures?

In the *Schweizerische medizinische Wochenschrift* for July 15th Dr. Gustav Peter, of the dermatological clinic in Zurich, crystallises the principal problem of venereal disease in the question, Is a policy of propaganda and education alone sufficient to promise the suppression of this disease? In other words, Can an appeal to the individual's reason and good sense be so fruitful that compulsory measures can be omitted? His emphatic answer in the negative is largely the expression of the experience he has gained at the dermatological polyclinic in Zurich during two and a half years. The 1000 male patients who attended for venereal disease in this period were classified according as the results of free treatment were good, bad, or indifferent. In 763 cases the disease was gonorrhoea and in 396 it was syphilis. Thus there was a total of 1159 cases, the additional 159 representing the combination of gonorrhoea and syphilis in the same patient. In 143 cases of the 1000 reinfection occurred more than once. As Dr. Peter's tables show, the prognosis, as careful investigation of every case indicated, was good only in 52 per cent.; in 47 per cent. it was bad. Unsatisfactory as these figures are, he does not consider them misleading, and he quotes Philip, who, in 1914, analysed the histories of 1433 insured patients suffering from syphilis in Hamburg. In 89 per cent. they were found to be most inadequately treated, and only in 11 per cent. was even comparatively effective treatment carried out. A significant feature of the Zurich figures was the fact that in as many as 35 per cent. the age of the patient was under 25 years. Another deplorable fact was the frequent incidence (15 per cent.) of reinfection. These are the findings which have driven Dr. Peter to conclude that "the main cause of the failure of our efforts is the psychological factor." How, he asks, can we expect to prevent by educational and voluntary methods healthy persons from contracting venereal disease when we find that those already infected are so callous as not to carry out the treatment nor to practise the advice given them? Not only do they neglect treatment, but in

many cases they expose themselves to reinfection, and thus render nugatory whatever results previous treatment may have achieved. In this connexion it is deplorable that neither syphilis nor uncomplicated gonorrhoea gives rise to much pain; as a rule, the treatment is considerably more painful than the disease. And this contributes not a little to the triumph of folly and indolence over the well-intentioned and oft-repeated advice of experts. Hence the necessity for legislation ensuring compulsory treatment, and Dr. Peter prophesies that compulsion will prove to be the only effective solution of the problem of venereal disease.

CANADA.

(FROM OUR OWN CORRESPONDENT.)

Medical Pioneers in Western Canada.

AT the fifty-first annual meeting of the Canadian Medical Association, held in Vancouver during June, the President, Dr. Robert E. McKechnie, of that city, dealt chiefly in his presidential address with medical affairs in Western Canada, which he described as one vast country stretching from Winnipeg to Vancouver. Dr. McKechnie considered the medical outlook of Eastern Canada to be insular, whereas in the western provinces, with their uniform conditions of rapidly developing country and similar problems to face and overcome, they had a better perspective, were free from local prejudice, and could more easily criticise and appreciate themselves. When it is realised, however, that this sentiment was expressed at the annual meeting of the national medical body, many of whose members had journeyed from the Far East to the Far West, the idea of any material sectional cleavage in the medical profession in Canada cannot very well be entertained. Speaking for British Columbia, the President told of the first medical men who are shown by any existing record to have practised in the Pacific province—William Anderson, surgeon on H.M.S. *Resolution*, and John Law, surgeon on the *Discovery*, both of whom accompanied Captain Cook on his first and last voyage in 1778. Anderson died of consumption, and Cook appointed a Mr. Samual, surgeon's first mate, as surgeon to the *Discovery*, Law being removed to the *Resolution*. In 1792 Spanish warships entered the Straits of Juan de Fuca, having with them one Louis Galvez, surgeon, who was reputed very skilful. In the same year Captain Vancouver appeared on the scene as an agent of Britain, and took the country from the Spanish. Accompanying him were three surgeons, the most important member of that group being Menzies, surgeon's mate to Watson on the *Chatham*. He was trained at Edinburgh, and equally skilful as scientist and physician. At the end of the voyage Vancouver complimented him, saying that no life had been lost through sickness for a period of three years. Menzies made great collections of plants, &c., and these are to-day gathered in three places—the British Museum, Kew, and the herbarium of the Botanical Society of Edinburgh. From 1792 there is a blank in the medical history of British Columbia. In 1850 a new generation of medical men began to arrive, the first being John Sebastian Helmcken, surgeon to a ship of the Hudson Bay Company, which came round the Horn. Dr. Helmcken is still living in the city of Victoria at the ripe age of 95 years. He was born in London, England, in 1825, and was educated at Guy's Hospital. At one time he was the leading practitioner from San Francisco to the North Pole, there being no other doctor throughout that vast region. Among other pioneers in medicine were John C. Davie, Simon J. Tunstall, J. W. Powell, O. M. Jones. The profession to-day in all western provinces is counted, not by hundreds, but by thousands of men, many of them in isolated localities, not perhaps making money, but devoting their lives to the service of humanity.

Canadian Society of Anaesthetists.

The Canadian Society of Anaesthetists has recently been organised for the purpose of promoting the science

of anaesthesia, its practice and teaching. As nearly all large Canadian hospitals now have specialists in anaesthesia on their staffs, it is fitting that these should form themselves into an organisation for mutual benefit and study. The officers of the society are: President, Dr. Samuel Johnston, Toronto; Vice-President, Dr. William Webster, Winnipeg; secretary-treasurer, Dr. Wesley Bourne, Montreal. The first annual meeting will probably be held in Montreal in October of this year, at the time of the meeting of the American Clinical Congress of Surgeons.

American College of Surgeons.

The Clinical Congress of the American College of Surgeons will be held in Montreal about Oct. 20th. It is expected that it will be the largest medical convention ever held in Canada. The programme is chiefly clinical in character, and as the clinics will be held at the hospitals admission will be by registration and ticket. Many eminent surgeons are expected from Canada, the United States, France, and Great Britain.

Changes in the Canadian Medical Services.

Major-General Carleton Jones, sometime Director of the Canadian Medical Services, has taken up his residence in Italy. Major-General John Taylor Fotheringham, C.M.G., who succeeded him, has recently retired from the service and re-entered private practice in Toronto as consulting physician. Before laying down his office General Fotheringham issued a farewell statement expressing his deep sense of the constant loyalty and high efficiency of the Canadian service as a whole, both overseas and in Canada, and of his indebtedness, as officer administering the service in Canada, to the personnel as a whole.

Toronto, Sept. 2nd.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Dangers of Fresh Milk for Babies.

SOME time ago attention was called by an article in the periodical, *Kosmos*, to the ill-effects of fresh cow's milk upon babies in a number of districts, and recent investigations have proved the statements there made to be true. It has been ascertained that in certain districts of the country the high infant mortality remains almost unaffected in spite of the strenuous efforts of local health authorities. Close examination reveals the facts that gastro-intestinal troubles are in the majority of cases the underlying cause of death and that these illnesses are traceable to the milk with which the babies are fed. As such troubles are restricted to certain districts, the cows and their food were suspected. It was actually found that certain plants and weeds eaten by cows in the pastures contained substances passing over into the milk and acting as severe irritants to the infantile human gastro-intestinal canal without causing discomfort to the animal itself. The following plants were frequently found to be detrimental: meadow-saffron, corncockle, common convolvulus, and vetch. These weeds proved to be distinctly dangerous, especially if growing on sandy or lime-containing ground. Individual idiosyncrasy or predisposition played a marked rôle in the production of untoward effects. During the war, when the number of cows diminished rapidly in this country and goats were kept in increasing numbers, such irritative effects were noted more often, as the latter animals are even less sensitive to irritant herbs. The effectiveness of the campaign against infant mortality is more apparent in the low-lying parts of the country, where the above-mentioned plants are less apt to flourish. Agricultural circles, as well as the medical profession, should exercise vigilance in this matter.

The Housing Problem.

A serious menace to the welfare of the population, especially in Vienna, has arisen in the problem offered by the condition of buildings used for human habitation. Vienna, the capital of a dwarf State of six millions of inhabitants (of whom fully one-third dwell in the city

itself) cannot expand as it ought to. Before the war the annual increase of dwellings amounted to 9000, and even at that figure there was a noticeable scarcity of lodgings. For six years nothing has been built, partly owing to the absence of all labourers at the front, partly owing to the fantastic rise in prices of material and labour which set in as soon as the war came to an end. When the soldiers returned marriages took place at the rate of hundreds a day, with the result that at present over 25,000 dwellings, or 2500 houses, are needed to accommodate these newly-married couples alone. The old houses become slowly but surely dilapidated. Sanitary arrangements and renovations are not being attended to because the rent of lodgings is being kept at the pre-war level by legislation, and slums cannot be abolished. The housing problem is becoming a burning question, and the only remedy—money—is not forthcoming. Owing to overcrowding, to the insufficiency of nourishment, and to the prevalence of tuberculosis the poorer classes of the population—the middle classes, the brain-workers, the State and municipal officials—are unable to grapple with the needs of the time, and are rapidly sinking in the social scale. The municipality and the State have made arrangements for the erection of about 400 houses, containing about 2000 dwellings, for their officials and workers, but much time will elapse before these lodgings can be fit for use, and in any case their number is sadly insufficient.

Decrease of Hunger Œdema.

The Union of Sick Clubs reports to the Board of Health that hunger Œdema is disappearing steadily and not too slowly amongst the 343,000 labourers of both sexes who are members of the Union. During the worst years of the war the dystrophic conditions were also noted amongst other sections of the population, as well as in other countries—Roumania, Germany, and Serbia. In Vienna during 1917 the reported cases amongst members of the Union of Sick Clubs alone averaged 115 per month, the maximum of 220 being reached in July and August. In 1918 the average was 114 per month, the July figure being 234; the maximum was 259, in August. Then the number fell constantly, and in 1919 the average was 42 cases, the worst months being March with 72 and May with 78. In 1920, January, with 20 cases, was the worst month, and the figure dropped to 6 in July. But cases still occur, and the disease must be absolutely eradicated not only from amongst the labourers, but also from amongst other classes of the population. As an illustration of the actual conditions, it might be mentioned here that the American Famine Area Assistance Committee, which has done such noble work amongst our half-starved children, has decided to open a "war kitchen" for professors and lecturers of the University, because the majority of these men are unable to procure the materials and the fuel necessary for a regular household. Cases of hunger Œdema are not absolutely unknown amongst the so-called middle classes.

Drop in Price of Pharmaceutical Articles.

The Government has taken a decided step in keeping down, or rather bringing down, the exorbitant prices of medicines and allied articles by procuring a large quantity of different remedies—aspirin, iodine, codeine, morphine, cocaine—in foreign markets and distributing it by means of the Central Apothecary Board to the various chemists and dispensaries. This stock will be sold to the public at prices far lower than the present ordinary price of these articles, and the poorer classes will thus be able to obtain medical help and relief besides the advice given them gratuitously in the hospitals. Hospitals will also be allowed to dispense such remedies free of charge in certain cases of poverty. No small part of the sufferings of our population were due to the fact that genuine medicines were not obtainable, products of lesser efficiency being substituted for them. Cod-liver oil, for instance, is even now so scarce that a gift from a Norwegian Society consisting of about three barrels of this precious substance was received with the utmost pleasure by our Board of Health for distribution in the children's hospitals.

"Andi alteram partem."

AMERICA AND POST-GRADUATE MEDICAL STUDY IN LONDON.

To the Editor of THE LANCET.

SIR,—Perhaps your readers will be interested in what was to me a startling item of news. A young qualified physician from one of the Middle Western States of the United States came to my office saying that he was on his way to do some advanced work at Vienna. He said that a committee in Chicago had circularised the physicians in his State, saying that they had organised an excursion for physicians to go to Vienna for study as before the war American physicians were accustomed to do. The committee gave assurances that they had prepared the way for the reception of these physicians in Vienna and for the offering of old-time facilities. Furthermore, the committee were prepared to aid in securing steamer passages and passports. I expressed surprise that one, in the present famished condition of Vienna, and in view of the disruption of the war, should attempt to go there for study. I then presented the facilities for advanced medical study in Great Britain and in London. My acquaintance replied that it was the impression among the physicians in his community that the British medical faculty were not particularly cordial in the reception of American students, and that despite the fact of the great clinical advantages of London the post-graduate work was so submerged and intermingled with the under-graduate work that the opportunities were not comparable with those which were formerly enjoyed in Vienna and Berlin.

Inasmuch as it is one of the functions of my office to promote the exchange of American professors and the interchange of migrating students with the British, and to direct here the stream of American students earlier going to the Continent, it seems as if I ought to apprise the medical schools and hospitals of the above fact.

If properly organised I believe no better authorities or facilities for post-graduate work exist anywhere than here. But unless something is done at once it is evident that our late enemies will soon recover the patronage and prestige that they had before the war. If the British-American fellowship of our nations is so important to the future peace and progress of the world, as is frequently proclaimed, how important it is that not only our universities but also our great professions cooperate in making personal contacts and professional studies in common.

This is a critical and opportune moment. Evidently there is no time to lose. My office, which represents some 60 of the leading Universities and Colleges of the United States, the Institute of International Education in New York, the American Council on Education, the American Association of University Professors, and the Association of American Colleges, is maintained primarily for the service of American professors and students, particularly graduate students. A cordial welcome has thus far been given by the British to the office and our students, but in the field of medicine it seems to me particularly desirable that the interest already shown by the British brethren should be applied immediately to the further organisation and promotion of post-graduate study.—I am, Sir, yours faithfully,

GEORGE E. MACLEAN.

Director, British Division of the American University Union in Europe.
50, Russell-square, London, W.C.1, Sept. 17th, 1920.

*. The general object of the American University Union in Europe, as stated on its notepaper heading, is to serve as a bond between the Universities of the United States and those of European nations, especially by encouraging the attendance and advancing the welfare of American students at the Universities of France, Great Britain, and Italy, in such ways as the trustees may see fit. We comment elsewhere on Mr. MacLean's letter.—ED. L.

THE MASS TREATMENT OF HOOKWORM INFECTION.

To the Editor of THE LANCET.

SIR,—In your issue of July 10th, which I have only just seen, Dr. S. T. Darling takes up the position that diagnosis of ankylostome infestation by the finding of ova in the stools being, as now carried out by the lay microscopist, expensive, time-consuming, and untrustworthy, and disinfestation by anthelmintics being impossible, and indeed unnecessary, all that is needful, once infestation has been detected in a community, is promiscuous treatment, preferably by two half treatments of oil of chenopodium, the staff then passing on to another area, leaving the inhabitants of the first greatly improved in health.

The position, were the premisses sound, would be capable of defence. The premisses are not sound. It is true that as ordinarily carried out microscopic diagnosis is all that Dr. Darling says of it. I have shown, for example, that about half a c.cm. of stool must be examined in the case of Indians of the labouring class before a negative diagnosis of hookworm infestation can be made, since in mild infestations only one egg may be present in somewhat less than that quantity. Further, the strained and centrifuged residue from an aqueous suspension of this quantity of stool must be spread over an area of 24 square inches, if full visibility is to be obtained and accuracy of diagnosis ensured.

Of course, such examination in sparse infestations is expensive, time-consuming, and, since the requisite quantity of stool is probably never examined, untrustworthy. But why not blame the technique and look for something better? I have been able to show in this connexion that by a simple and easily learnt manipulation for washing the sediment of a stool, obtained by fulfilling certain simple conditions as to the straining and centrifuging of a faecal suspension, there is removed practically all of the faecal matter, which, however, carries away with it about one-sixth of the ankylostome ova present, and there is left on two square inches of slide five-sixths of the ova from half a cubic centimetre of stool, and practically nothing else. This technique has been labelled "levitation." Is it expensive? That is scarcely the point. The question should be, Is it worth the money? That depends upon a variety of matters, and will be mentioned below. Does it save time? In sparse infestations it saves hours. Is it trustworthy? In the hands of two Indian medical men, trained in levitation and working in jails of the United Provinces of India, it gave an infestation of 84.4 per cent.; while in 326 post-mortem examinations made in that part of India the reports of which have been collated by the Rockefeller Foundation, the percentage of infestation was 82.2. These figures, together with a consistent failure to find ova in a second $\frac{1}{2}$ c.cm. of levitated stool if the first have proved negative, suggest that levitation will give a positive diagnosis in fresh stools in all cases where there are ova in the bowel: that it is in itself time-saving and accurate.

The lay microscopist can be trained to accuracy, and by a modification of what I have described as the "standardising method" he can be checked the whole time, so that it is his administrator's fault and his own good fortune if his falls from grace be not speedily detected. These men are not relatively expensive if employed in numbers in a central laboratory. But this implies that stools must be preserved if they are to reach such a laboratory in a state suitable for levitation. Figures so far as available (they require addition) show that by the use of certain preservatives, and certain preservatives only, levitation gives good results in preserved stools. In such a central laboratory the work will be arranged in shifts, the cheap lay microscopist dividing his time between the attention-straining microscope and the centrifuge and levitation technique which allow of rest to mind and eye, an arrangement which will definitely add to accuracy of work.

The problem of accurate, rapid, and cheap diagnosis seems much nearer satisfactory solution, to put the matter at its worst, than Dr. Darling's paper suggests:

but before we know where we stand there are a number of techniques to be standardised and compared, always remembering that a technique which with certainty concentrates only 10 per cent. of ova may yet for general or particular occasions be better than one which similarly concentrates 80 per cent., provided that the former can start with ten times as much stool as the latter. This being the position regarding diagnosis, it is surely inadvisable, one might perhaps say retrograde and unscientific, to undertake indiscriminate treatment without preliminary diagnosis. Further, when death follows, not necessarily results from treatment, as must occur from time to time when millions are involved, the procedure simply invites trouble from the suspicious and disaffected, who are sure to say, "Here is a man killed by a dose of medicine given when there was no evidence that he even required it." Such incidents are not in the best interests of mass disinfection.

Regarding treatment, it is well that the unsatisfactory character of our best anthelmintics, as disclosed by accurate diagnosis, should be emphasised. Dr. Darling feels that it justifies the policy of making no attempt to render a community entirely free from infestation. It is well to realise that in the absence of a satisfactory type of latrine this entails acquiescence in certain and rapid re-infestation with all its grave consequences. It seems no answer to say that this will recur in any case, for it is reasonable to assume that the more complete the disinfection the fewer foci of infection will remain, and the longer and greater will be the benefit to the community before the whole work has to be undertaken again. That complete disinfection is unnecessary for the individual cannot, in view of the present trend of medical knowledge and opinion on infections generally, and on this infestation in particular, be accepted without proof. Many will at least agree that the deliberate retention in a given area of unnecessary foci of infection is a grave sanitary sin; while it is unquestionable that to give immigrants a routine treatment and then loose them on a country in the belief that this procedure will keep that country free from ankylostomes can only lead to grave disappointment.

But the crux of the whole problem is, by its title, excluded from Dr. Darling's paper. It is this. So long as there exists no sanitary latrine suitable for the single hut so long is it impossible to eliminate ankylostome infestation from the rural tropics. An insanitary latrine is as dangerous as an insanitary filter, and there has latterly actually appeared in the literature evidence of what one suspected must be occurring—namely, dejectional infestation—infestation, that is, acquired during defaecation, and indeed from the very latrine which was not suspected to be capable of conveying it.

The essentials of the problem seem to be these. The benefits which can, at least temporarily, be conferred upon hundreds of millions of persons should not be withheld because our methods are admittedly imperfect; so long as it is clearly recognised that they can only be temporary and correspondingly costly. At the same time, research must be urgently pushed through on at least three matters: 1. The determination of the best method of mass diagnosis by the standardisation and comparison of the techniques recommended for the removal of faecal matter from ova, techniques which enable eggs to be detected rapidly and certainly in all cases where they are present in the stools. 2. The search for a drug which will in a single dose, and without risk to the host, remove all hookworms. 3. The designing of a cheap, effective, sanitary, and fool-proof latrine suitable for a single family in the rural tropics.

The morbidity, poverty, infertility, stunting of body and mind, and the mortality resulting from ankylostome infestation in the hundreds of millions of persons affected is in the aggregate so great that the question of cost ought to be of minor importance when any line of investigation is promising in fruitfulness. This is, unfortunately, by no means to say that it will be, although it is one of the most attractive commercial propositions which have ever been offered to any Government.—I am, Sir, yours faithfully,

CLAYTON LANE,

Ealing, W., Sept. 15th, 1920. Lieutenant-Colonel, I.M.S. (retd.).

THE LATE DR. LEONARD GUTHRIE.

To the Editor of THE LANCET.

SIR,—A photograph of the late Dr. Leonard Guthrie is wanted by many friends at this hospital, but difficulty is being experienced in procuring one suitable for reproduction. I should be glad if readers of THE LANCET could tell me of any photographs in existence, and particularly grateful for the loan of one. Great care would be taken to preserve and return it; reproduction would not injure the print in any way.

I am, Sir, yours faithfully,

H. W. BURLEIGH,

Secretary and General Superintendent, Hospital for Epilepsy and Paralysis, Maida Vale, London, W.

Sept. 17th, 1920.

The Services.

POSTPONEMENT OF COMPETITIVE EXAMINATION IN THE INDIAN MEDICAL SERVICE.

It is announced that no competitive examination for the Indian Medical Service will be held during 1921. Arrangements for the appointment of candidates by selection in India and in England will, however, be continued. The question of resuming the examination in January, 1922, is under consideration, and an announcement will be made on the subject early next year.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. R. St. G. S. Bond has been appointed Professor of Hygiene at the R.N. Medical School, Greenwich.

ROYAL ARMY MEDICAL CORPS.

Capt. R. C. Matson is placed on the half-pay list on account of ill-health contracted on active service.

Temp. Capt. E. G. M. Gilchrist relinquishes the acting rank of Major.

Temp. Capt. J. E. Measham to be Lieutenant and to be temporary Captain.

Lieut. (Hon. Capt.) F. D. Ross-Keyt, from T.F. Res. (Arty.), to be Lieutenant.

Officers relinquishing their commissions:—Temp. Lieut.-Cols. (and retain the rank of Lieutenant-Colonel) E. Goodall (on ceasing to be employed at the Welsh Metropolitan Hospital), J. B. Byles (on ceasing to be employed at the Brook War Hospital); Temp. Major N. G. Cooper (and retains the rank of Major); Temp. Capt. F. Hannigan; Temp. Capt. (and retain the rank of Captain) W. Garton, R. Hamilton, J. N. M. Sutherland, J. R. Watson; Temp. Lieut. F. T. Allen (and retains the rank of Lieutenant).

TERRITORIAL FORCE.

Capt. (acting Lieut.-Col.) H. S. Beadles relinquishes his acting rank on ceasing to be specially employed.

Capt. E. J. Boome to be Major.

Capt. S. J. Fielding, from T.F. Reserve, to be Captain.

Capt. T. B. McKee resigns his commission and is granted the rank of Major.

Capt. D. A. Wilson resigns his commission, and retains the rank of Captain.

Capt. H. H. L. Ellison (late temporary Captain, R.A.M.C.), to be Captain.

1st London Sanitary Company: Lieut. F. Rae to be Captain.

The King has approved the retirement of Col. C. N. C. Wimberley, who retains the rank of Colonel.

INDIAN MEDICAL SERVICE.

Temp. Capt. Khaliq Dad, Bhola Nath, and Mohammad Afayat Khan relinquish their commissions and are granted their rank.

DEATHS IN THE SERVICES.

Lieut.-Col. Arthur Holbrook Nott, I.M.S., who died suddenly on August 20th from heart failure while on a visit to the Engadine, at the age of 58, received his first commission in 1887, and reached the rank of Lieutenant-Colonel 20 years later. He had held the post of Civil Surgeon at Murshidabad.

AN International Economic Conference will be held at Caxton Hall, Westminster, London, S.W., from Oct. 11th to 13th. The subjects for discussion will include the present obstacles to economic reconstruction, international finance, problems of coal, transport, and raw material, and coöperative production and distribution as a measure of reconstruction. Visitors and delegates are expected from America, Austria, Belgium, France, Germany, Holland, Italy, and Switzerland. In connexion with the Conference a public meeting will be held in the Central Hall, Westminster, on Oct. 13th, at 8 p.m. Further particulars and tickets can be obtained from the Secretary, Fight the Famine Council for Economic Reconstruction, 150, Southampton-row, London, W.C. 1.

Obituary.

SIR JOHN WILLIAM BYERS, M.D., M.Ch. R.U.I.,
M.A.O. (*hon. causâ*),

PROFESSOR OF MIDWIFERY, GYNÆCOLOGY, AND DISEASES OF
CHILDREN, QUEEN'S UNIVERSITY OF BELFAST.

WE regret to announce the death, in his sixty-seventh year, of Sir John Byers, which took place at his home in Belfast on Sept. 20th as a result of cerebral hæmorrhage, closely following on the death of his intimate friend, Mr. Robert Campbell, whose obituary notice he wrote. Prominent in most movements that concern the public weal, he was closely associated with the campaign against tuberculosis and with the reduction of infant mortality, while as a gynæcologist and paediatrist he had more than a local reputation. For many years he was a valued correspondent of THE LANCET, where he placed his wide knowledge of men and things without stint at the service of his profession. A man of warm heart and holding strong views, he ever strove to be just to those who differed from him.

Born at Shanghai in 1853, John William Byers was the son of the Rev. John Byers, a China missionary, and of Margaret Byers, née Morrow, one of a group of famous women educationists, who became LL.D. Dub., and founded the Victoria College at Belfast. His academic record was equally distinguished. He attended the Royal Academical Institution, and later Queen's College in Belfast, and became at the latter senior scholar in natural science as well as in medicine, midwifery, and medical jurisprudence. Both at the B.A. and M.A. examinations he was gold medallist and first in the honours list. At the M.D., M.Ch. R.U.I., in 1878, he again took high honours. Beginning to practise in Belfast, he was appointed physician to the Hospital for Sick Children, holding that position until 1893, when he was appointed professor of midwifery in Queen's College, Belfast, a post which he held for 16 years. In the meantime he became examiner in obstetric medicine at the Royal University of Ireland. In 1909 he was appointed to the chair of midwifery, gynæcology, and diseases of children at Queen's University, which he was still occupying at the time of his death.

His interest in public affairs took Byers to many important gatherings at home and abroad. He presided over the International Congress of Obstetrics and Gynæcology held at Geneva in 1896, over the Section of Obstetrics at the annual meeting of the British Medical Association at Cheltenham in 1901, over the Section of Physical Education and Training in Personal Hygiene at the International Congress of School Hygiene held in London in 1907, and over the Conference on the Hygiene of Childhood at the Royal Sanitary Congress held at Belfast in 1911. Nearer home he naturally occupied the chair at meetings of the Ulster Medical Society and the Belfast Branch of the Irish Medical Association. His practical interest in child welfare was shown in an eloquent introductory address to the students of the London School of Medicine for Women in 1906, when he foreshadowed the important part which women were soon destined to play in the solution of public health questions. Lady Byers did as a matter of fact establish the first babies' club in Belfast some two years later. Sir John Byers was himself one of the first to see and inculcate the importance of antenatal supervision of motherhood in avoiding the causes leading to stillbirth or death in the early months of independent existence. The human element was to him an essential part of maternal welfare, and he was never party to any separation of mother and child or to the substitution of institutional for home life.

As diversions from professional study literature and folk-lore were among Byers's hobbies; his contributions to the Belfast Literary Society were always of interest if not of permanent value. The Belfast Natural History and Philosophical Society also owed him much.

Sir John Byers received the honour of knighthood in 1906. To Lady Byers and three sons who survive him we tender heart-felt sympathy.

PROFESSOR ARMAND GAUTIER.

THERE was in France no more ardent worker for chemical science in its relation to medical advance than Emile Justin Armand Gautier, whose death in his eighty-third year was recently announced. Gautier had been President of the Academy of Science at the Institute of France and occupied the chair of Mineral and Organic Chemistry for 45 years in the Paris Faculty of Medicine. His father, a medical man, gave him the incentive to scientific work, and he chose chemistry as a professional career with conspicuous success. He took a warm interest in chemical forensic questions, and became impressed with the possibilities of error in analytical conclusions based upon the extraction and identification of alkaloids. Reactions which he obtained with extracts from the cadaver appeared identical in certain respects with those given by well-defined bodies of vegetable origin now regarded as alkaloids. But Gautier, while he succeeded in isolating certain bases from putrescent material and in showing that they gave responses to chemical reagents akin to those by which plant alkaloids were identified, adduced no direct evidence to show that these substances were toxic. He called them ptomaines, and food poisoning has been frequently attributed to such bodies. We now have good reason to believe that food poisoning, when it occurs, is of bacterial origin, due not to poisons produced outside the body, but rather to infection from the bacteria themselves when introduced into the human organism. But Gautier undoubtedly deserves credit for the attention given to food poisoning, which led to our present enlightenment. His views were not narrow, any more than the inquiries which he undertook into the widespread distribution of arsenic, the impurities of the air of towns, the "faking" of wines, and the constituents counting for evil in tobacco smoke. He was also a vigorous investigator of many questions in chemistry relating to molecular construction and constitution. By his death France has lost a notable savant.

URBAN VITAL STATISTICS.

(Week ended Sept. 18th, 1920.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at nearly 18 million persons, the annual rate of mortality, which had been 9.9, 10.0, and 10.3 in the three preceding weeks, fell to 10.2 per 1000. In London, with a population of nearly 4½ million persons, the annual death-rate was 9.8, or 0.1 per 1000 below that recorded in the previous week, while among the remaining towns the rates ranged from 3.5 in Exeter, 3.6 in Ealing, and 4.3 in Lincoln, to 15.4 in Bury, 15.5 in Wigan, and 16.6 in Rotherham. The principal epidemic diseases caused 280 deaths, which corresponded to an annual rate of 0.8 per 1000, and comprised 182 from infantile diarrhoea, 54 from diphtheria, 19 from whooping-cough, 13 from scarlet fever, 7 from enteric fever, and 5 from measles. Whooping-cough caused a death-rate of 1.6 in Wolverhampton. The deaths from infantile diarrhoea, which had been 150, 171, and 171 in the three preceding weeks, rose to 182, and included 46 in London, 15 in Liverpool, 13 in Sheffield, 9 in Hull, and 7 in West Ham. There were 2953 cases of scarlet fever and 1591 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, against 2633 and 1484 at the end of the preceding week. The causes of 21 of the 3494 deaths in the 96 towns were uncertified, of which 4 were registered in Birmingham and 2 each in Leicester, Liverpool, and Preston.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2½ million persons, the annual rate of mortality, which had been 11.1, 9.8, and 11.2 in the three preceding weeks, rose to 11.3 per 1000. The 270 deaths in Glasgow corresponded to an annual rate of 12.7 per 1000, and included 10 from infantile diarrhoea, 5 from small-pox, 2 from diphtheria, and 1 each from enteric fever and scarlet fever. The 63 deaths in Edinburgh were equal to a rate of 9.6 per 1000, and included 1 fatal case each of scarlet fever, diphtheria, and infantile diarrhoea.

Irish Towns.—The 107 deaths in Dublin corresponded to an annual rate of 13.4, or 0.7 per 1000 below that recorded in the previous week, and included 12 from infantile diarrhoea and 3 from whooping-cough. The 114 deaths in Belfast were equal to a rate of 14.4 per 1000, and included 9 from infantile diarrhoea, 3 from scarlet fever, and 1 each from enteric fever and diphtheria.

Medical News.

ST. MARY'S HOSPITAL MEDICAL SCHOOL APPEAL.

The authorities of this medical school have issued a booklet of 15 pages in which the urgent needs of the school and the arguments in support of the appeal are set out. The importance of medical education to the country and the increased expenditure entailed by modern requirements in teachers, accommodation, laboratories, and equipment are explained in terms comprehensible to the lay public, for whom the book is intended. The need for rebuilding the school is urgent, but with great economy and the use of existing walls it is estimated that the cost will not exceed £30,000. This estimate does not include a block for the pathological institute, where the director, Sir Almoth Wright, and his staff still work in laboratories adapted from wards originally intended for midwifery beds. It is proposed to supply more adequate accommodation for the institute and to release these wards for their original purpose. This part of the scheme is estimated to cost £40,000; the rest consists in the endowment of chairs of (1) Industrial Medicine; (2) Hygiene, Public Health, and Preventive Medicine; and (3) Pharmacology; and of four scholarships of £250 each per annum for promising graduates. The appeal is addressed especially to the heads of great industries and to those interested in medical education in general and in the co-education of men and women, as the continuance of this system at St. Mary's is dependent on the provision of increased accommodation. A preliminary appeal committee consists of Mrs. Lloyd George, Lady Rhondda, Lord Linlithgow, Sir Robert Kindersley, Sir Clifford Allbutt, Sir Malcolm Morris, Mr. Guy Kindersley, Mr. A. R. Prideaux, Sir Almoth Wright, and Mr. T. M. Taylor. Donations, which, if desired, may be earmarked for a particular object, should be sent to Mrs. Lloyd George at 10, Downing-street, London, S.W.1., or to the Dean at the Medical School.

OPENING OF SESSION IN LONDON MEDICAL SCHOOLS.

The following announcements have reached us:—

King's College Hospital Medical School.—The session will be opened on Oct. 1st, at 3 P.M., when Mr. F. Richardson Cross will deliver the introductory address.

London (R.F.H.) School of Medicine for Women.—The introductory address will be given at 8, Hunter-street, Brunswick-square, London, W.C., by Miss A. Maude Royden on Revolutionary Thought at 3 P.M. next Friday, Oct. 1st.

Middlesex Hospital Medical School.—The introductory address will be delivered by Professor T. Swale Vincent at the Scala Theatre on Friday next, Oct. 1st, at 3 P.M., after which prizes will be distributed by Earl Beatty.

St. Mary's Hospital Medical School.—The opening of the winter session will take place on Friday next, Oct. 1st, at 3 P.M., when Professor J. G. Adami will distribute the prizes in the library. As already announced, the annual dinner of past and present students will be held at the Connaught Rooms at 7 P.M., Sir John Goodwin presiding. In the course of the evening a testimonial will be presented to Dr. M. M. Bird, the retiring medical superintendent of the hospital.

Westminster Hospital Medical School.—The introductory address will be given at 4 P.M. on Thursday next, Sept. 30th, by Dr. A. M. Gossage in the Board Room of the Hospital.

WEST LONDON POST-GRADUATE COLLEGE.—The autumn session opens on Monday, Oct. 11th, when Sir William Bull will give the inaugural address at 5 P.M. Medical practitioners are cordially invited to attend.

LONDON HOSPITAL MEDICAL COLLEGE.—A special course of lectures open to students and post-graduates has been arranged by the Surgical Unit for Wednesdays and Fridays in October. Two lectures on Some Points in Orthopaedic Surgery will be given by Mr. T. H. Openshaw on Oct. 6th and 8th; Dr. J. H. Sequeira will lecture on Tumours of the Skin on Oct. 13th and 15th; Mr. Hugh Lett will lecture on Enlargement of the Prostate on Oct. 20th and 22nd; and Mr. Richard Warren will lecture on Surgery of the Lung on Oct. 27th and 29th. All lectures will be delivered in the Units' Lecture Theatre, London Hospital, E., at 4 P.M.

MEDICAL DEFENCE UNION.—The annual meeting was held at 11, Chandos-street, London, W., on Sept. 16th, Sir John Tweedy, the President, occupying the chair, when a conspectus of the year's activities was presented. During 1919-20 the work of the Union had been steadily maintained, many important actions being successfully defended in the courts, while equally satisfactory had been the number of cases settled out of court to the advantage of the members. Membership had steadily increased in spite of an advance in the subscription

to £1. 584 new members were elected as compared with 169 in 1918. The solicitors reported that 138 cases had been referred to them, 86 of this total relating to general and miscellaneous matters; the large proportion of cases falling under this head was explained by the fact that many members had required assistance in putting their affairs in order after returning from war service. The financial report showed an increase in subscriptions of £711 over the corresponding figures for 1918. On Dec. 31st, 1919, the surplus assets over the liabilities, after making the necessary reserve for income-tax, were just over £9000. By a new arrangement coming into force on Jan. 1st, 1921, each member of the Medical Defence Union will be provided with indemnity against damages and costs awarded against him to the extent of £2,500 in any case which is undertaken by the Council of the Union.

THE Hughlings Jackson lecture of the Section of Neurology will be delivered at the Royal Society of Medicine by Dr. Henry Head, F.R.S., on Oct. 7th, at 8.45 P.M. Dr. Head has chosen as his subject, "A New Conception of Aphasia."

A MEETING of the General Council of the National Council for Combating Venereal Diseases will be held on Tuesday, Oct. 12th, at 3.30 P.M., the place of meeting to be announced later.

CHARING CROSS HOSPITAL MEDICAL SCHOOL.—The annual dinner of past and present students will be held in the Adelaide Gallery, Gatti's Restaurant, on Monday, Oct. 4th, at 7 for 7.30 P.M.

LONDON (R.F.H.) SCHOOL OF MEDICINE FOR WOMEN.—A luncheon will be held at the Fishmongers' Hall on Tuesday, Oct. 19th, at which representative men and women will meet to support the school. Sir Alan Anderson, honorary treasurer of the school, will preside, and will be supported by Dr. Mary Charlton, Miss Aldrich-Blake, Dr. Jane Walker, Lady Barrett, Dr. Louisa Garrett Anderson, and other medical women.

MANCHESTER TOWN-PLANNING SCHEME.—An inquiry on behalf of the Ministry of Health was held at Manchester on Sept. 15th into a proposed town extension scheme, involving 5269 acres situated chiefly on the southern side of the city. The total cost of the scheme would be over £3,300,000, and at least 50 years would be required for its completion. The principal features are the construction of 56 new streets, several of which would be 100 feet wide, running from three main arterial roads; the limitation to a maximum of 16 in the number of houses to the acre; and the relegation of new smoke-producing factories to a particular area. Provision is made for controlling the density of future building in the area, to preserve as far as possible the open character of districts not yet over-crowded. Building of warehouses and factories, except such as produced no inconvenience, would be confined to the eastern portion. Power is also sought to prohibit offensive advertisements and to prevent gardens or allotments from being kept in a state of nuisance.

CAPITAL VALUE OF MEDICAL PRACTICE: THE DARTFORD SCHEME.—The Dartford scheme to maintain the capital value of a general practice originated at a meeting of the practitioners of Dartford and district, when the question was raised of the approaching loss of the capital value of practices, a loss which becomes more and more serious as larger classes are brought into insurance. The original scheme was purely local, but it was considered possible to develop on the same lines a national scheme whereby doctors might insure payment of the capital value of their practices to their representatives or to themselves when they retired from active work. The scheme was therefore brought before various bodies concerned with medical politics, and has now been officially adopted by the Kent Local Medical and Panel Committees, and is recommended for adoption to their constituents. If these approve the Minister of Health will be asked for his sanction. The scheme is that every year there shall be taken from the county or borough medical pool before its distribution a sufficient sum to pay to each doctor who has retired a sum equal to one year's purchase of his panel practice. This sum will, of course, have been provided by the practitioners to whom the amount would otherwise have been distributed, but each of these will be able to draw a like sum when he retires. In effect, on his retirement each practitioner will be able to sell his practice to his fellows for one year's purchase. The actual terms of the resolution moved by Dr. M. W. Renton at the meeting of the Kent Committees on Sept. 8th, and approved by them, is as follows:—

That in view of the following facts—i.e.: (a) That a retiring practitioner had formerly a saleable asset in the goodwill of his practice, and (b) that this asset is, or may be, diminished by the coming into operation of National Health Insurance, and (c) that the Kent Local Medical and Panel Committees are extremely

anxious to provide against the economic difficulties which are certain to ensue, and particularly in the case of sudden death or incapacitating illness of practitioners, and (d) that for administrative reasons no payments could conveniently be arranged except from the medical pool, which is not under the control of these committees.

These committees advise the practitioners of Kent to authorise them to strongly urge upon the Minister of Health that he should, as early as possible, give his permission, make regulations or promote such legislative enactments as may be required to authorise the following payment, i.e.:

(a) A payment of one year's purchase price of his panel practice in the event of a practitioner's death or his retirement from practice owing to old age or infirmity.

(b) A lesser payment if he retires for the purpose of starting practice elsewhere—e.g., in Harley-street.

It is pointed out in an explanatory note that the lesser payment is on a sliding scale and is necessitated by the possibility that a practitioner might relinquish his practice just for the purpose of claiming payment and then move elsewhere and repeat the process. It is considered to be further justified in that the primary object of the scheme is to protect widows and wives of those who suddenly fall ill and to provide a little capital for the doctor's old age. Further details are given of the scheme as at present drafted and of the advantage to be anticipated from its adoption.

HOSPITAL CONDITIONS IN BRISTOL.—At the half-yearly meeting of the Bristol General Hospital Mr. Herbert M. Baker, the chairman, was able to report a substantial increase in subscriptions and donations, which totalled £20,000, as against £16,000 during the corresponding period of last year. It is true that expenditure showed an even greater rise, but the figures warrant a hope that the voluntary sources of income may yet prove equal to the strain that is being put on them.—A number of representatives of the boot and shoe industry and of other factories in the Kingswood district of Bristol have declared their intention of forming a committee to organise collections in factories and workshops for the support of the voluntary hospitals. The Cossham Hospital is a general hospital for East Bristol, founded only a few years ago on a very generous endowment by the will of the late Mr. Handel Cossham; it is now on the verge of debt. It is hoped that whether by voluntary aid or by subsidies from such bodies as the Ministry of Pensions or the Gloucestershire County Council this hospital may still be saved from falling into debt.

BRITISH HOSPITALS ASSOCIATION MEETING AT BIRMINGHAM.—A meeting of this association was held on Sept. 16th at the General Hospital, Birmingham, and was attended by representatives from the West Midland region, comprising Herefordshire, Shropshire, Staffordshire, Warwickshire, and Worcestershire. Sir Arthur Stanley presided, and emphasised the need to strengthen the organisation in view of the legislation anticipated in the future. The Ministry of Health, he said, welcomed the organisation and was anxious to retain the voluntary system. Sir Napier Burnett dealt with the present and future financial needs of voluntary hospitals. He estimated that something like a million pounds was required to put the hospitals of the country back into the position they occupied in 1914. He could see no relief from present anxieties while so many hospitals relied on their present methods of raising money by circulars and spasmodic appeals. Those methods were losing power, and the public was weary of the multiplicity of appeals. It was necessary to supplement the appeal to the ordinary subscribers by a regular stream of weekly collections from the employees of factories, workshops, and business houses, and by guaranteed amounts from employers. The workers were willing to pay a voluntary levy, but the hospitals must create the machinery for its collection. The amount of workmen's contributions per available bed ranged from £1 in some towns to £51 in others. It would have to be explained that the hospitals were of value to a patient's family, to his employer, to insurance companies, to the State, to the municipality, and to a patient's fellow-workers. The almoner system of obtaining contributions from patients might be found effective in many cases. Insurance companies gave meagre financial support in return for what the hospitals were doing for the insured. Municipalities, too, took advantage of the voluntary institutions without making an adequate return. Thus burdens were placed upon the voluntary principle which it was not intended to carry. It was the duty of the State to see that the necessary accommodation was provided for its workers, who might be injured in building up the work of the nation. Some form of State subsidy was required in return for the work which the hospitals did for the State. But it should bear no direct relationship to maintenance. For if it did, as a capitation grant increased, so would voluntary support recede, until in the course of a few years the hospitals would be financed entirely by the State. The subsidy should be limited to providing the requisite additional hospital accommodation, a certain amount of equipment, payment towards

the cost of training nurses, and the encouragement of pathological and bacteriological research. Municipally controlled hospitals had proved to be more costly than voluntary institutions. He suggested that in order to overcome present difficulties some of the Poor-law hospitals should be loaned or handed over for use as general hospitals.

RED CROSS CONFERENCE AT BIRMINGHAM.—A conference promoted by the British Red Cross Society and the Order of St. John of Jerusalem was held in Birmingham on Sept. 16th with the object of bringing county organisations into closer touch with headquarters. The Lord Mayor presided and Sir Arthur Stanley gave an address. He said he was certain that much voluntary work must be done in time of peace if the country were to be prepared for war. He did not want his successors to go into the next war as they did into the last, with about £7000 and a set of patterns, almost all of which were wrong, as their whole equipment. When the war ended they were left with a joint war committee and a considerable sum of money. It was realised that the union of the two principal Red Cross agencies should continue and a joint council had been formed. This was followed by the suggestion to form in every county a joint committee, which should co-opt representatives of the other kinds of work they hoped to do in peace time, the object being to co-ordinate the various branches of voluntary work and to prevent the enormous amount of overlapping and waste of effort that existed at present. Outlining the work of a peace programme, Sir Arthur Stanley said that obviously the first consideration would be services in connexion with the men of His Majesty's Forces who were sick and wounded during the war. Much required to be done, and the joint societies ought to stand to the pensions hospitals in exactly the same position as they stood to the military hospitals during the war. Assistance would also be given to orthopaedic clinics and curative establishments. Child-welfare and tuberculosis work must also be undertaken. A motor ambulance service was being established in the counties; 300 or 400 motor ambulances had been brought back from the battle fronts and placed in various districts, and they had a scheme for covering the country with a network of ambulances, so that no patient should be more than 15 miles from an ambulance centre. In reply to questions as to the future status of V.A.D.'s Sir Arthur Stanley said that an answer was being pressed for from the Army Council. It might be taken as certain that the V.A.D.'s would remain part of the Territorial Force, and that their recruiting and training would be left to the two societies.

Appointments.

DUNCAN, D., M.B., Ch.B. Glasg., has been appointed Certifying Surgeon under the Factory and Workshop Acts for North Nottingham.

WILLAN, R. J., F.R.C.S., Temporary Honorary Surgeon to the Royal Victoria Infirmary, Newcastle-upon-Tyne.

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary.—Jun. M.O. £500.

Aberdeen University.—Lectureship in Bacteriology. £600.

Barnsley, Beckett Hospital and Dispensary.—Sen. H.S. £250.

Barnstaple, North Devon Infirmary.—H.S. £200.

Battersea General Hospital (Incorporated), Battersea Park, S.W.—

Third Res. M.O. £200.

Bedford County Hospital.—Asst. H.S. £150.

Birmingham, Monks Hill Colony for Epileptics and Feeble-minded.—

Res. M.O. £700.

Birmingham, Queen's Hospital.—Three H.P.'s, three H.S.'s, Obstet.

and Ophthal. H.S., and Cas. H.S. £90 each.

Brighton, Royal Sussex County Hospital.—Asst. H.S. £150.

Cancer Hospital (Free), Fulham-road, London, S.W.—H.S. £150.

Carnegie Dunfermline Trust.—Asst. M.O. £500.

City of London Hospital for Diseases of the Chest, Victoria Park, E.

—Tuberc. O. £600.

Colchester, Essex County Hospital.—H.S. £200.

Colonial Service.—M.O.'s for West African Medical Staff, Govern-

ment Service in Malaya, East African Protectorates, West Indies

(including British Guiana), Fiji, and the Western Pacific, &c.

Countess of Dufferin's Fund, India, Women's Medical Service.—

Three Medical Women. Rs. 350 per mensem.

Downpatrick, Down District Asylum.—Two Asst. M.O.'s. £300.

Dumfries, Crichton Royal.—Asst. P. £350.

East London Hospital for Children and Dispensary for Women,

Shadwell, E.—H.S. and H.P. £125.

Glamorgan County Asylum, Bridgend.—Jun. Asst. M.O. £350.

Glasgow District Mental Hospital, Gartloch, Gartcosh.—Asst. M.O.

£350.

Hospital for Consumption and Diseases of the Chest, Brompton,

S.W.—Asst. Anæsth. £25. Also Asst. Res. M.O. £150.

Hospital for Sick Children, Great Ormond-street, W.C.—Cas. M.O.

£200. Also Asst. Cas. M.O., H.S., and H.P. £50 each.

Huddersfield Royal Infirmary.—Two Asst. H.S.'s. £150 each.

Hull Royal Infirmary.—Asst. H.S. £150.
 Ingham Infirmary and South Shields and Westoe Dispensary.—
 Jun. H.S. £175.
 Johannesburg, South African School of Mines and Technology.—
 Professorship of Vet. Anat. £860.
 Leeds City.—Asst. M.O. £500.
 Leeds City Hospitals, Seacroft.—Asst. M.O. £300.
 Leyton Urban District Council Education Committee.—Oculist, £125.
 Liverpool, Royal Southern Hospital.—H. P. and H.S. £100.
 Macclesfield General Infirmary.—Res. H.S. £200.
 Maidstone, Kent County Mental Hospital.—Jun. Asst. M.O. £300.
 Maidstone, Kent County Ophthalmic Hospital.—H.S. £300.
 Manchester, Hulme Dispensary, Dale-street, Stretford-road.—
 H.S. £400.
 Manchester Northern Hospital for Women and Children, Park-place,
 Cheetham Hill-road.—H.S.
 Manchester, St. Mary's Hospitals for Women and Children.—H.S.
 for Whitworth Park Hospital. £100.
 Metropolitan Asylums Board Infectious Hospitals Service.—Jun.
 Asst. M.O.'s. £515 6s.
 Monmouthshire Asylum, Abergavenny.—Jun. Asst. M.O. £350.
 Montrose Royal Asylum.—Asst. M.O. £350.
 Newcastle-upon-Tyne, Hospital for Sick Children.—Two Hon.
 Asst. S's.
 Norfolk County Mental Hospital, Norwich.—Sec. Asst. M.O. £350.
 Northampton, County Borough Education Committee.—Female Asst.
 Sch. M.O. £500.
 North Riding County Asylum, Clifton, York.—Temp. Asst. M.O.
 7s. per week.
 Oxford, Radcliffe Infirmary and County Hospital.—H.P. £200. Also
 Administrator. £600.
 Plymouth, South Devon and East Cornwall Hospital.—H.S. £200.
 Pontypridd Urban District Council.—Female Asst. M.O. £550.
 Prince of Wales's General Hospital, Tottenham, N.—H.P. and H.S.
 £200. Jun. H.S. and Jun. H.P. £120.
 Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—
 H.S. £100.
 Royal Eye Hospital, St. George's Circus, S.E.—Sen. and Jun. H.S.'s
 £100 and £75. Also Clin. Asst.'s.
 St. Mary's Hospital for Women and Children, Plaistow, E.—
 Hon. S.
 Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S.
 £150.
 Sheffield Royal Infirmary.—H.S. £150.
 Somerset, Wells Asylum.—Asst. M.O. £300.
 South Mimms, near Barnet, Clare Hall Sanatorium.—Res. Asst.
 M.O. £300.
 Sydney University, New South Wales, Australia.—Chair of Dentistry.
 £1100. Also Chair of Physiology. £1150.
 University College Hospital Surgical Unit, University-street,
 W.C.—Third Asst. £300.
 Ventnor, Royal National Hospital for Consumption and Diseases of
 the Chest.—Asst. Res. M.O. £300.
 West Hartlepool, Cameron Hospital.—H.S. £300.
 Westminster Hospital, S.W.—P. or S. Dis. Skin.
 Westmorland County Education Committee and Kendal Borough
 Education Committee.—Dent. Practitioner. £500.
 Wigan Infirmary.—Hon. P. and Asst. Hon. P.
 Wilts County Council.—Asst. County M.O.H. and Asst. Sch. Med.
 Inspec. £600.
 Wolverhampton County Borough Education Committee.—Asst.
 Sch. M.O. £500.
 Wolverhampton and Staffordshire General Hospital.—H.S. £200.
 Worcestershire County Council.—Sch. Oculist. £550.
 Worcester County and City Mental Hospital, Powick.—Jun. Asst.
 M.O. £350.
 The Chief Inspector of Factories, Home Office, S.W., gives notice
 of a vacancy for a Certifying Surgeon under the Factory and
 Workshop Acts at Southall.

Births, Marriages, and Deaths.

BIRTHS.

POULTON.—On Sept. 17th, at The Downs, Woldingham, Surrey, the
 wife of E. P. Poulton, M.D., F.R.C.P., of a daughter.
 WHITE-COOPER.—On Sept. 7th, at "North Ford," Dartmouth,
 Devon, the wife of W. R. White-Cooper, M.B., B.S. Lond., of a
 son.

MARRIAGES.

GRANT—HODGKINSON.—On Sept. 15th, at St. Giles' Church, Bradford-
 on-Tone, Somerset, Dr. Gerald Wallace Grant, M.C., to Dorothy
 Beevor Milnes, only daughter of Mr. and Mrs. Edwin Beevor
 Hodgkinson, of Risdon, Bradford-on-Tone.
 LAWRY—GREGORY.—On Sept. 15th, at the Parish Church, Poynton,
 Cheshire, James Littleton Lawry, M.D. B.S. Lond., M.R.C.S.
 Eng., L.R.C.P. Lond., to Dorothy Evelyn, youngest daughter
 of the late William Gregory, of Sheffield.
 MOSER—BYGOTT.—On Sept. 16th, at Wem, Salop, Captain Richard
 Moser, late R.A.M.C., to Ellen, elder daughter of Mrs. Bygott
 and the late Edward Bygott, of Wem.

DEATHS.

BYERS.—On Sept. 20th, in Belfast, Sir John William Byers, M.D.,
 M.Ch. R.U.I., aged 66.
 MCKINNON.—On Sept. 15th, at King's College Hospital, Dr. A. A.
 McKinnon, of British Guiana.
 PIGEON.—On Sept. 3rd, killed in action in Mesopotamia, John
 Walter Pigeon, M.B., B.C. Camb., Captain, Indian Medical
 Service, aged 33 years.
 SHOPPEE.—On Sept. 15th, at Warwick-road, Cliftonville, Margate,
 Edward Collett Shoppee, M.R.C.S. Eng., L.R.C.P. Lond.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of
 Births, Marriages, and Deaths

Medical Diary.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London
 Hospital, Hammersmith, W.
 MONDAY, Sept. 27th.—2 P.M. Mr. B. Harman: Eye Department.
 2 P.M., Mr. MacDonald: Surgical Out-patients.
 TUESDAY.—2 P.M., Dr. Burnford: Medical Out-patients. 2 P.M.,
 Mr. T. Gray: Surgical Out-patients.
 WEDNESDAY.—2 P.M., Mr. Addison: Operations. 2 P.M., Dr.
 Owen: Medical Out-patients.
 THURSDAY.—2 P.M., Mr. Baldwin: Orthopaedic Department.
 2 P.M., Mr. B. Harman: Eye Department.
 FRIDAY.—2 P.M., Mr. T. Gray: Surgical Out-patients. 2 P.M.,
 Dr. Pernet: Skin Department.
 SATURDAY.—10 A.M., Dr. A. Saunders: Medical Diseases of
 Children. 2 P.M., Dr. Owen: Medical Out-patients.
 Daily.—10 A.M., Ward Visits. 2 P.M., In-patient, Out-patient
 Clinics and Operations.
 ST. MARK'S HOSPITAL, City-road, E.C.
 Course of Lectures on Proctology.
 TUESDAY, Sept. 28th.—2.30 P.M., Dr. F. Crookshank: Mucous
 Colitis.
 WEDNESDAY.—2.30 P.M., Mr. H. Graeme Anderson: Fissure.
 THURSDAY.—2.30 P.M., Sir Gordon Watson: Operative Treat-
 ment of Haemorrhoids. 4.30 P.M., Dr. S. S. Wyard:
 Pathological Specimens.
 FRIDAY.—4.30 P.M., Mr. L. E. C. Norbury: Sigmoidoscopy.
 SATURDAY.—2.30 P.M., Mr. W. B. Gabriel: Demonstration of Cases.
 MANCHESTER FRENCH HOSPITAL POST-GRADUATE LEC-
 TURES, 24, Acomb-street (behind Whitworth Park).
 THURSDAY, Sept. 30th.—4.15 P.M., Dr. A. C. Magian: Ovarian
 Pregnancy.

Notes, Short Comments, and Answers to Correspondents.

ON THE NEED OF A NEW TECHNIQUE IN ANTHROPOLOGY.¹

BY PROFESSOR KARL PEARSON, M.A., LL.D., F.R.S.

WHAT is it that a young man seeks when he enters the university—if we put aside for a moment any social advantages, such as the formation of lifelong friendships associated therewith? He seeks, or ought to seek, training for the mind. He seeks, or ought to seek, an open doorway to a calling which will be of use to himself, and wherein he will take his part, a useful part, in the social organisation of which he finds himself a member. Much as we may all desire it, in the pressure of modern life, it is very difficult for the young man of moderate means to look upon the university training as something apart from his professional training. Men more and more select their academic studies with a view to their professional value.

Prospects of the Student of Anthropology.

We can no longer combine the senior wranglership with the pursuit of a judgeship; we cannot pass out in the classical tripos and aim at settling down in life as a Harley-street consultant; we cannot take a D.Sc. in chemistry as a preliminary to a journalistic career. It is the faculties which provide professional training that are crowded, and men study nowadays physics or chemistry because they wish to be physicists or chemists, or seek by their knowledge of these sciences to reach commercial posts. Even the very Faculty of Arts runs the danger of becoming a professional school for elementary school teachers. I do not approve this state of affairs; I would merely note its existence. But granted it, what does anthropology offer to the young man who for a moment considers it as a possible academic study?

There are no professional posts at present open to him and few academic posts.² There is little to attract the young man to anthropology as a career. Is its position as a training of mind any stronger? The student knows if he studies physics or chemistry or engineering that he will obtain a knowledge of the principles of observation, of measurement, and of the interpretation of data, which will serve him in good stead whenever he has to deal with phenomena of any kind. But, alas, in anthropology, while he finds many things of surpassing interest, he discovers no generally accepted methods of attacking new problems: "quot homines, tot sententiæ."

The Type of Student Needed.

The type of man we want in anthropology is precisely the man who now turns to mathematics, to physics, and to astronomy—the man with an exact mind who will not take statements on authority and who believes in testing all things. To such a man anthropometry—in all its branches, craniometry, psychometry, and the wide field in which body and mind are tested together under dynamic conditions—forms a splendid training, provided his data and observations are treated as seriously as those of the physicist or astronomer by adequate mathematical analysis.

Such a type of man is at once repelled from our science if he finds in its text-books and journals nothing but what has been fitly termed "kindergarten arithmetic." Why, the other day I saw in a paper by a distinguished anthropologist an attempt to analyse how many individual bones he ought to measure. He adopted the simple process of comparing the results he obtained when he took 10, 20, 30 individuals. He was not really wiser at the end of his analysis than at the beginning, though he thought he was. And this notwithstanding that the whole matter had been thrashed out scientifically by John Bernoulli two centuries ago, and that its solution is a commonplace of physicist and astronomer!

An Exact Technique.

How can we expect the scientific world to take us seriously and to treat anthropology as the equal of other sciences while this state of affairs is possible? What discipline in logical exactness are we offering to academic youth which will compare with that of the older sciences? What claim have we to advise the State until we have introduced a sounder technique and ceased to believe

that anthropometry is a science that any man can follow, with or without training? As I have hinted, the problems of anthropology seem to me as subtle as those of physical astronomy, and we are not going to solve them with rusty weapons, nor solve them at all unless we can persuade the "brainy boys" of our universities that they are worthy of keen minds. Hence it seems to me that the most fertile training for academic purposes in anthropology is that which starts from anthropometry in its broadest sense, which begins to differentiate caste and class and race, bodily and mental health and disease, by measurement and by the analysis of measurement.

Once this sound grounding has been reached the trained mind may advance to ethnology and sociology, to prehistory and the evolution of man. And I shall be surprised if equal accuracy of statement and equal logic of deduction be not then demanded in these fields, and I am more than half convinced, nay, I am certain, that the technique the student will apply in anthropometry can be equally well applied in the wider fields into which he will advance in his later studies. Give anthropology a technique as accurate as that of physics, and it will forge ahead as physics have done, and then anthropologists will take their due place in the world of science and in the service of the State.

Francis Galton's Warning.

Francis Galton has a claim upon the attention of anthropologists which I have not. He has been President of your Institute, and he spoke just 35 years ago from the chair I now occupy, pressing on you for the first time the claims of new anthropological methods. In Galton's words: "Until the phenomena of any branch of knowledge have been submitted to measurement and number it cannot assume the status and dignity of a science." Have we not rather forgotten those warning words, and do they not to some extent explain why our universities and learned societies, why the State and statesmen, have turned the cold shoulder on anthropology?

This condition of affairs must not continue; it is good neither for anthropology, nor for the universities, nor for the State if this fundamental science, the science of man, remains in neglect. It will not continue if anthropologists pull together and insist that their problems shall not fail in utility, that their scientific technique shall be up to date, and that anthropological training shall be a reality in our universities—that these shall be fully equipped with museums, with material, with teachers and students.

Planning for the Future.

It is almost as difficult to reform a science as it is to reform a religion; in both cases the would-be reformer will offend the sacrosanct upholders of tradition, who find it hard to discard the faith in which they have been reared. But it seems to me that the difficulties of our time plead loudly for a broadening of the purpose and a sharpening of the weapons of anthropology. If we elect to stand where we have done a new science will respond to the needs of State and society; it will spring from medicine and psychology, it will be the poorer in that it knows little of man's development, little of his history or prehistory. But it will devote itself to the urgent problems of the day.

The future lies with the nation that most truly plans for the future, that studies most accurately the factors which will improve the racial qualities of future generations either physically or mentally. Is anthropology to lie outside this essential function of the science of man? If I understand the recent manifesto of the German anthropologists, they are determined it shall not be so. The war is at an end, but the critical time will be with us again, I sadly fear, in 20 to 30 years. How will the States of Europe stand then? It depends to no little extent on how each of them may have cultivated the science of man and applied its teaching to the improvement of national physique and mentality.

Let us take care that our nation is not the last in this legitimate rivalry. The organisation of existing human society with a view to its future welfare is the crowning task of the science of man; it needs the keenest-minded investigators, the most stringent technique, and the utmost sympathy from all classes of society itself. Have we, as anthropologists, the courage to face this greatest of all tasks in the light of our knowledge of the past and with our understanding of the folk of to-day? Or shall we assert that anthropology is after all only a small part of the science of man, and retreat to our study of bones and potsherds on the ground that science is to be studied for its own sake and not for the sake of mankind?

I do not know what answer you will give to that question, yet I am convinced what the judgment of the future on your answer is certain to be.

Mr. W. McAdam Eccles, of St. Bartholomew's Hospital, who has lately removed an "included foetus" from a male infant, aged 8 months, would be glad to hear of any similar case in which the specimen has been preserved.

¹ Being the concluding section of the presidential address to the Anthropological Section of the British Association.

² In London, for example, there is a reader in physical anthropology who is a teacher in anatomy, and a professorship in ethnology, which for some mysterious reason is included in the faculty of economics, and is, I believe, not a full-time appointment.

PUBLIC HEALTH IN NEW ZEALAND, 1918-19.

IN the report on Public Health and Hospitals and Charitable Aid in New Zealand for the year ending March 31st, 1919, Dr. T. H. A. Valintine, Inspector-General of Hospitals and Chief Health Officer, details his proposals for reorganising and strengthening the department (which include an increase in the number of districts to eight, with 12 medical officers of health), and reviews the general sanitary conditions of the Dominion. A statement of the expenditure borne by the Government in connexion with the influenza epidemic shows that the total amounted to £182,659. In addition to this a sum of £75,374 has been allotted as an annual relief to widows and orphans, and in some cases widowers with children. There was an increase in diphtheria and cerebro-spinal meningitis during the year under review, but scarlet fever, enteric fever, and tuberculosis showed decreased prevalence.

The pandemic of influenza prevailed in New Zealand with considerable severity in November and December, 1918. In these two months 5471 deaths were directly attributable to this disease, the provinces of Auckland and Wellington suffering most, with 3127 deaths between them. Dr. R. H. Makgill, district health officer for Auckland, who makes a special report on the subject, states that there were two distinct waves of infection, the first reaching its maximum about August or September, with an abnormal but not alarming mortality, the second developing in the first two weeks of November, with a virulence far in excess of anything that had hitherto been experienced. This "division into first and second waves, with undue morbidity [fatality] of the second wave, was experienced all over the world, and the greatest intensity of the second wave was almost synchronous in countries so widely separated as Britain and New Zealand." Alluding to the fact that, "whereas in ordinary epidemics the power fails as the wave recedes, this one showed a recrudescence power," Dr. Makgill remarks that there is nothing stable about the virulence of an infective organism, and this applies to the influenzal group as to others. The conditions were very favourable to the spread of disease.

"Huge bodies of men gathered together in training camps throughout the world, and then hurried overseas in conditions of unavoidable overcrowding, and the concentration in Europe of these overseas bodies of men has never occurred before on such a scale. The massing together of recruits drawn from country districts has produced an ideal field for the cultivation of infective organisms, since these men have not had time to acquire immunity to these organisms."

Popular opinion attributed the outbreak to the arrival of the mail steamer *Niagara* with many cases on board, but Dr. Makgill shows good reasons against this view.

The low degree of resistance to pneumonia among New Zealand troops has been demonstrated in Britain. Dr. Makgill considers this to be—

"probably the result of the general healthful condition of life and climate [in New Zealand], whereby our population fails to acquire that natural immunity to disease of the type which the slum-dweller derives from constant struggle with invading organisms. It is doubtless to this that we owe the very violent character of the outbreak."

This is an argument that seems to cut both ways. Is the slum-dweller likely to have a greater resisting power to infection generally than the countryman? Of the total 5471 deaths from influenza, 2719 occurred in persons between the ages of 25 and 40; that is, 49.71 per cent. of the deaths in 23.88 per cent. of the population. The actually highest ratio was in the age period 30 to 35 (1010 deaths, or 11.19 per 1000 in 8.18 per cent. of the population). Males suffered much more than females (6.49 compared with 3.48 deaths per 1000); this agrees with the general experience. In the age groups from 25 to 40 the deaths numbered 1826, or 52.36 per cent. of male deaths in 22.03 per cent. of the male population. Among females between 25 and 40 there were 893 deaths, or 45.43 per cent. of female deaths in 25.64 per cent. of the female population.

The progress of the epidemic is clearly described, and the increase in virulence emphasised.

"To the student of bacteriology there is nothing inconceivable in the possibility of an organism, by rapid transference from case to case under favourable surroundings, being changed from a harmless saprophyte to a very virulent infective parasite."

Though not always recognised, this is eminently reasonable in regard to many of the specific infections, the causative organisms under certain conditions developing a progressively increasing infective power. Dr. Makgill traces the relationship between the first and second epidemic waves, and describes the preventive measures adopted. Systematic treatment by the use of weak solutions of zinc sulphate in an inhalation chamber was found during two and a half years' experience in the military camps to be highly satisfactory; the proportion of "severe" cases was reduced from 50 per cent. to 22 per cent. among men who were treated daily for three successive days. "Frequent washing out of the nose and mouth with simple salt solution is probably as valuable a family remedy as any which can be suggested."

"THE DOCTOR'S REFERENCE LIST."

A CONVENIENT little book for keeping on the consulting-room table is provided by "The Doctor's Reference List," now in its eleventh edition. Addresses of homes and hospitals for special cases, convalescent homes, inebriate retreats, sanatoriums, private asylums, nursing homes, and benevolent institutions are classified and indexed for ready reference; summaries are included of the Inebriate, Lunacy, and Insurance Acts, as well as other enactments which affect the medical man in regard to the advice which he may give his patient. The value of the book would be increased by careful revision. Names of secretaries are still given who have vacated office by death or other causes. The scope might usefully be widened to include schools for mental defectives, welfare and venereal centres, and similar institutions. The publishers are Messrs. George Pulman and Sons, Thayer-street, London, W., and the price is 1s.

MINERS' SAFETY LAMPS.

MISUNDERSTANDING may possibly arise from our reference to the illumination from safety lamps in an annotation on Nystagmus (THE LANCET, Sept. 11th, p. 562). The light from these lamps certainly becomes less as work proceeds, but this is due rather to an indirect than a direct effect of coal-dust. Dust clogs the gauze which is above the glass cylinder in front of the flame; this clogging interferes with the ventilation of the lamp and so affects the flame. The glass cylinder becomes less transparent owing to deposition of smoke from a flame which is not burning brightly.

SALVIA OFFICINALIS.

SAGE has been credited with many medicinal virtues, and as a popular simple is still used by country folk, though it is not now officially recognised in the British Pharmacopœia. Among its reputed uses were those of a gargle for sore-throats and a cleanser of the teeth, and Mrs. Grieve, of "The Whins" Medicinal and Commercial Herb School and Farm, Gerrards Cross, who has compiled a very interesting pamphlet on the healing virtues of the sage, suggests that the plant might be tried in pyorrhœa. The salvia was so esteemed in time past as to give rise to the monkish line:

Cur moriatur homo cui salvia crescit in horto?—

a variant of the old English saying:

He that would live for aye
Must eat sage in May.

Mrs. Grieve deals with the cultivation of the plant, its preparation for market, chemical constituents, use in medicine, and the preparation of food, and includes some account of other members of the great labiate order. The price of the book is 7½d. post-free from the author.

THE EFFECT OF CASTRATION ON UTERINE CONTRACTIONS.

THE effects of castration on the automatic movements of the uterus in the guinea-pig have recently been studied by Mons. Athias, of Lisbon, and in the *Journal de Physiologie et Pathologie* he describes the results obtained by observing the movements of the excised uterus in well-oxygenated Tyrode's fluid—akin to Ringer's fluid—kept at 35° C. The uterus in new-born females shows almost no automatic movements; when excised the uterus contracts and slowly relaxes. The motor functions become distinct a month after birth, the movements beginning 10-20 minutes after the preparation is placed in the nutrient fluid and lasting for 24-48 hours. The movements of the surviving uterus show three periods. There is an initial contraction, during which the relaxed muscle shows contractions which steadily decrease; in 2-6 hours this passes into a period of relaxation, when, as the tonus diminishes, the contractions become more marked and more regular, lasting 24-48 hours; there follows a period of increased tonus which precedes final termination of the contractions. There is no fundamental difference between virgin and previously pregnant uteri. The uterus of the later stages of pregnancy and of parturient animals show specially powerful contractions. In 23 animals of different ages—virgin and previously pregnant—double ovariectomy was performed. During the first 4-6 months after the operation no difference was noted. Only after 9 months, when the activity of the excised uterus showed changes, was atrophy observed. The initial contraction then lasted longer, and the period of relaxation was considerably diminished; the contractions were small and scarcely perceptible, and the terminal period was shortened. The atrophy of the uterus and the accompanying diminished activity occurred considerably later when the animals were castrated during or immediately after pregnancy. In five animals—5-34 days after castration—the ovaries of other females were grafted subcutaneously. In these cases the function of the uterus remained as long as functional ovarian tissue was unabsorbed, which, according to the author, might be for a period of 2-3 years, but the ovarian tissue may disappear within 20 months. It would seem, therefore, that the presence of the ovary is essential for the maintenance of the normal function of the uterus.

SYNOPSIS OF MEDICINE

FOR PRACTITIONERS AND STUDENTS.

By **H. LETHEBY TIDY**, M.A., M.D., B.Ch. (Oxon.), F.R.C.P. (Lond.), Assistant Physician, St. Thomas's Hospital Physician, Great Northern Central Hospital.

The Publishers have issued this volume, in response to many requests, on the same lines as Mr. Hey Groves' popular *Synopsis of Surgery*.

From the Preface.—The book aims at providing a synopsis of such principles of medicine as are of importance at the present time. A wider scope has been adopted than merely the classification of the most prominent details of each disease. Symptoms have been enumerated and explained, and the pathology of the disease and references to the most probable or best-known theories have also been included. At the same time it is hoped that those data which are of greatest importance have been clearly indicated. The sections on treatment have been planned to afford a ready reference to a reasonable procedure, and no attempt has been made to give numerous alternative methods or prescriptions.

From a Harley Street Specialist.—"The condition is to a great extent a psychological one, and the admirable results obtained by yourself and your parents have in my opinion been to a great extent due to your personal psychological influence over your subjects. You are at liberty to use this expression of my opinion." (This letter may be seen.)

SEQUEIRA'S DISEASES OF THE SKIN

"By the inclusion of all the important advances made in dermatology during the war, the book has been brought entirely up to date. The illustrations are numerous and good and the text not too complicated. It is concise, and each disease is dealt with methodically. This new edition deserves even greater success than the previous ones."—EDINBURGH MEDICAL JOURNAL.

London: J. & A. CHURCHILL, 7, Great Marlborough Street, W. 1.

Eastman Dupli-Tized X-Ray Film

Eastman Dupli-Tized X-Ray Film is so rapid that radiographs can be obtained by means of single flash exposures even when two intensifying screens are used. This enables clearly-defined images to be registered of those internal organs the photographs of which are usually blurred when taken by prolonged exposure.

Made in the following sizes :

$6\frac{1}{2} \times 4\frac{3}{4}$, 8×5 , $8\frac{1}{2} \times 6\frac{1}{2}$, 10×4 , 10×8 , 12×10 ,
 14×11 , 15×12 , 17×14

For Safety and Mileage

FOR safety and economy the medical man's car should be shod with tyres of sure grip. The better the grip the longer the tyre lasts—the better the grip the fewer the skids.

The Beldam V Steel Studded Tyre is the best all-weather-all-roads gripping tyre in the world, because its indented steel studs flush with the rubber tread give it all the positive advantages of both rubber and steel-studded tyres. Have Beldam V Steel Studded Tyres on both back wheels and note how sure-footed your car will be, and how long the tyres will last.

Write for Booklet, "Testimony," which gives the opinions of experienced users.

Solquinate

SOLQUINATE, brand of Normal Oxyquinoline Sulphate, is a reliable antiseptic agent, non-poisonous, non-irritant, freely soluble in water to a clear solution. It is a powerful deodorising agent, very rapidly and effectively extinguishing all unpleasant odours, whether arising from vaginal or rectal discharges, bone affection, dental abscesses, or sloughing unhealthy ulcers.

SOLQUINATE is of great value as a lotion for rinsing the hands after examinations and operations. It does not attack the skin or nails.

The growth of *Staphylococcus Pyogenes* or *Bacillus Typhosus* is absolutely inhibited by a 1 in 10,000 solution, and development markedly checked by 1 in 20,000, and a 2/3 percent. (1 in 150) solution of Solquinate kills *Bacillus Coli* in five minutes, without causing any damage to tissues.

In obstetrical practice a solution of 1 in 1000 will be found superior to Carbolic Acid and Perchlorid lotions. Its innocuousness, combined with its deodorising and antiseptic power, gives it demonstrable advantages. There being no risk of staining, Solquinate may be regularly employed.

Prepared in Powder and 1½ grain Tablets.

Free Sample and Pamphlet sent to Medical Men, Nurses, and Hospitals on request.

Antikamnia Tablets

Strongly Recommended in: INFLUENZA & LA GRIPPE

For the headache, pain, and general soreness give a five-grain Antikamnia Tablet crushed with a little water; if the pain is very severe two tablets should be given. Repeat every 2 or 3 hours as required. One single ten-grain dose is often followed by complete relief.

NEURALGIA

In the Treatment of Neuralgia and Myalgic Pains Antikamnia Tablets are not only palliative, but, along with other measures, assist in ultimate cures; they also have a field of use in Rheumatic and Gouty Affections. In Neurasthenia, Hysteria, and Migraine they are a valuable adjuvant to the other recognised therapeutic measures.

LARYNGEAL COUGH

Frequently remains after an attack of La Grippe, and has been found stubborn to yield to treatment. There is an irritation of the larynx, huskiness, and a dry and wheezing cough, usually worse at night. The prolonged and intense paroxysms of coughing are controlled by ANTIKAMNIA & CODEINE TABLETS, and with the cessation of the coughing the laryngeal irritation subsides. Antikamnia Tablets are the least depressing of all the drugs that can exercise so extensive a control of pain, and also least disturbing to the digestive and other organic functions.

Analgesic.

Antipyretic.

Anodyne.

Antikamnia Preparations in 1-oz. packages only.

X VOLUNTARY TESTIMONY X

To the Skin Value of SAPON SOAPS

from members of the Medical and
Nursing Professions

TESTIMONIALS

A HARLEY STREET DOCTOR writes:

"I have found Sapon Soap most effective in 'Clearing' a muddy, greasy skin. In one particular case in which I advised its use, the result was very striking—a healthy pink complexion replacing a dull muddy one."

A DUBLIN DOCTOR writes:

"My daughter suffers from chronic seborrhoea of the arms, and this Soap has almost completely cured her. I look on it as a most valuable preparation in such cases, and have recommended it to several prominent medical men, who speak highly of it."

A LANCASHIRE DOCTOR writes:

"As I was suffering from a very irritable urticaria rash at the time I immediately set to work with the Russian Tar Soap, and I am glad to tell you that I have already experienced much relief."

A CHESHIRE DOCTOR writes:

"I find it admirable for sensitive and irritable skin, the result of Eczema, and will have great pleasure in recommending it."

A DROITWICH DOCTOR writes:

"I have given your Russian Tar Soap tablet you sent me a full testing in accordance with the printed instructions, and am pleased to assert it an admirable detergent, almost fascinating in its use and highly economical. It ought to command great success."

A NURSE at one of the principal Hospitals writes:

"It is really wonderful how it cleans up skin trouble, especially Eczema."

A MEDICAL NURSE writes:

"A little while ago I sent for one of your free samples of soap to try on a patient who had a very greasy skin. In the meantime I got a baby who showed every sign of soreness. I tried the very best of powders and creams. Last week I tried your soap and in two or three days baby was almost better, but we did not know whether it was the soap or the thick (pure) cream I was using until we went away for the day and had to use another soap. In the evening baby was very restless and red, and the next morning the whole trouble had returned; it is now settling down again nicely through the use of your Russian Tar Soap. Our water here is very hard, and I have passed on your other sample to another lady."

I felt I ought to thank you for the samples, for I should have been very grieved to have left a sore baby, yet I thought I had tried everything."

SAPON SOAPS are Entirely Different from all other Soaps

Free lather in any water. No scum which irritates the skin. Stops irritation from insect-bites and heals open wounds. Vermin will not touch skins washed with wonderful Russian Tar Soap.

Free samples will be sent to any member of the Medical Profession on application to

X **SAPON SOAPS LIMITED,** X

GLYKERON

or

Glyco-Heroin (Smith)

Glykeron and Glyco-Heroin (Smith) are synonymous appellations and are now known as such to all dispensing pharmacists.

GLYKERON is a transparent liquid of heavy density, amber color, agreeably aromatic odor, and pleasant taste. As a pharmaceutical product it is perfect, in that it is agreeable, effective, and absolutely stable, offering a therapeutic activity that is not impaired by either age or climatic changes.

As a respiratory sedative and cough-allaying agent, it is most potent and trustworthy. It affords unvarying results that can not be expected from extemporaneously prepared mixtures obtained through ordinary sources. It is the form in which the concerted influence of its several constituents on the respiratory system finds the most pronounced expression. It stimulates respiration, increases the fullness of inspiration and expiration, promotes the liquefaction of mucus, facilitates expectoration, and relieves pain.

It is particularly valuable in the treatment of cough, bronchitis, laryngitis, phthisis, pneumonia, whooping-cough, asthma, and inflammatory disorders of the respiratory tract.

The superiority of the preparation is evidenced by the extensive use made of it by physicians in all parts of the world.

Composition.

GLYKERON embraces the most active antispasmodic, balsamic, and expectorant agents. Its heroin content is one-half grain to each fluid ounce.

Dosage.

The adult dose of GLYKERON is one teaspoonful every two hours, or at longer intervals as the individual case requires. For children of ten years or more, the dose is from one-quarter to one-half teaspoonful; for children of three years or more, five to ten drops.

GLYKERON is obtainable, for dispensing purposes, in bottles of the following sizes only, and is not, under any circumstances, supplied in bulk or other form—

Large Size	-	-	-	-	16 fluid ounces each.
Small Size	-	-	-	-	3 fluid ounces each.

Phenoquin

(Southall)

The Original British Substitute for Atophan

Introduced in 1917

PHENOQUIN (Southall) chemically is 2-phenyl-quinolin-4-carboxylic acid (or phenyl cinchoninic acid), and was the first British representative of the pre-war German Atophan.

In the elimination of uric acid from the system, Phenoquin is specific.

Administered in acute gout, the attack is soon cut short, especially if the treatment is commenced at the first onset of pain. In chronic gout, too, and other forms of Arthritis, Phenoquin has proved most efficacious, rapidly increasing the amount of uric acid excreted.

Phenoquin has also proved of value in acute articular rheumatism and sciatica, and other indications for its use will present themselves constantly.

The dosage indicated is from 5 to 15 tablets daily (each containing 0.25 gramme, corresponding to a daily dose of 20 to 60 grains, or approximately 1 to 4 grammes.

A London Physician writes in the "British Medical Journal" (Aug. 25th, 1917):—

"Atophan" (the composition of which is stated to be 2 phenylchinolin 4 carbonic acid) eliminates uric acid, as shown a few hours after the first dose. The symptoms at once diminish, and soon disappear, as does the excess of uric acid on continuing the treatment. This week the first consignment of a British substitute has reached me. I tested the preliminary sample and found it innocuous and effectual."

The same Physician writes as under at a recent date:—

"I have distributed 30,000 tablets so far and have had no failure in good results."

In Bottles of 50 tablets, 6/- ; 100's, 11/- each.

Neo-Phenoquin

(Southall)

NEO-PHENOQUIN (Southall) is the lithium salt of 2-phenyl-quinolin-4-carboxylic acid (or phenyl cinchoninic acid) and has been introduced as a British improvement on the pre-war German Atophan.

Like Phenoquin it is specific in the elimination of uric acid from the system, but possesses the advantage of more immediate action owing to its solubility, and also that of a diminished tendency to set up any renal irritation.

THE DOSE IS THE SAME AS PHENOQUIN.

A London Physician writes:—"There is no doubt of the unique efficacy of the tablets. My friends and myself find unfailing success in their action."

In Bottles of 50 tablets, 7/6 ; 100's, 14/- each.

ORGANO-THERAPEUTICS

"Armour"

Quality with Reliability

THERE is no secret in the manufacture of Armour products. We claim, however, that all the Organo-Therapeutic preparations sold under the Armour label possess the highest quality with utmost reliability.

The opportunity of producing a superior article is ours, because we are in the position to handle enormous quantities of the raw material from which these preparations are made, before any deterioration can take place. In this advantage we are unique. The Armour Laboratory, situated in the largest abattoir in the world, is able to select only the very best raw material necessary for this work. It is also able to deal with this material without loss of time. For instance, in making GLYCEROLE OF PEPSIN we can treat the stomach of the animal with Glycerine while still warm, which results in a preparation that cannot be approached when made from isolated Pepsin.

Every Medical Man when prescribing these preparations should always specify "ARMOUR" on his prescription. He is thus sure of getting quality, reliability, and standardised dosage.

**Preparations
Indicated for Use in
Digestive Disturbances.**

Parotid Substance "Armour"
Pepsin "Armour."
Lactated Pepsin "Armour."
Elixir of Enzymes "Armour."
Diastase "Armour."
Duodenin (Duodenal Substance)
"Armour."
Pancreas Substance "Armour."
Trypsin Powder "Armour."
Amylopsin "Armour."
Nutritive Elixir of Peptones
"Armour."

Telephone: Holborn 5900 (Extension 34a).

COLLOSOL IODINE

containing Iodine in its most active condition. In all forms it is stainless, non-irritant, and avoids the disadvantages of Potassium Iodide and of Tincture of Iodine. It is prepared as:—

1. Aqueous; 2. Pasta; 3. Oil; 4. Ointment. Indications:

Rheumatism, Tuberculosis, Syphilis, Asthma, Eczema, and other Skin affections, and Chilblains.

Dose: 1 to 3 teaspoonfuls in water after meals, three times daily.

COLLOSOL FERROMALT

A combination of Pure Malt Extract with Colloidal Iron, rich in protein, diastase, and vitamins—the essentials for perfect carbohydrate metabolism. In this colloidal suspension Iron does not cause constipation or digestive troubles.

COLLOSOL FERROMALT with HYPOPHOSPHITES.

COLLOSOL FERROMALT with GLYCEROPHOSPHATES.

Dose: 1 to 4 teaspoonfuls, according to age, in water after meals.

COLLOSOL ARGENTUM

A non-toxic and non-irritant colloidal silver germicide and antiseptic, for general use, by topical application, injection and internal administration.

Indications: Septic and infective **Wounds, Influenza, Tonsillitis, Hæmorrhoids, Cystitis, Colitis, Gonorrhœa, Diarrhœa, Bacillary Dysentery**, and affections of the **Throat, Nose, Ear, and Eye.**

Dose: 1 to 2 teaspoonfuls in water, twice daily, fasting.

THE ORIGINAL COLLOIDAL PREPARATIONS FOR MEDICINAL USE.

CROOKES'

COLLOSOLS

Collosols are pure and stable colloidal solutions, isotonic and isomorphic with the elements of the body.

Collosols are tested by ultra-microscopic, bacteriological, and clinical experiment.

COLLOSOL MANGANESE

A colloidal suspension of Manganese for intramuscular injection, of proved value in septic conditions of the blood. Indications: **Furunculosis, Acne, Seborrhœic Eczema, Quinsy, and Gonorrhœa.** (Vide *British Medical Journal*, April 20th, July 20th, August 17th, and October 5th, 1918.)

COLLOSOL SELENIUM

A colloidal suspension of Selenium, for intramuscular injection. For use in cases of inoperable Carcinoma, &c. (Vide *British Journal of Surgery*, July, 1920, p. 50.)

COLLOSOL FERRUM

Collosol Iron is of established efficacy in Anæmia and Chlorosis. Given orally, colloidal iron is rapidly diffused in the stomach, and a large proportion of it is readily absorbed by the amino-acids formed in the process of digestion, and so hæmoglobin is synthesised.

Dose: 1 teaspoonful well diluted with water after meals.

COLLOSOL CUPRUM

A colloidal suspension of Copper, for intramuscular injection. For use in cases of inoperable Carcinoma, &c.

COLLOSOL SULPHUR

A colloidal sulphur suspension for internal administration and for use as baths, as Cream or as Oil. In this form taken internally the sulphur is entirely absorbed and avoids intestinal irritation.

Dose: 1 to 3 teaspoonfuls with water, during or after meals.

COLLOSOL ZINC CREAM

Non-greasy and non-irritant. Cremor Collosol Zinci being in the colloidal state, the zinc, on account of the infinite subdivision of the particles, has considerable penetrative power, particularly if the cream be applied and then gently rubbed in.

"Polyglandin"

Indicated in Hysteria & Uterine Disorders. Also in Neurasthenia, Melancholia & Sexual Neuroses

TREATMENT by pluriglandular extracts favours general secretory activity, and many cases of apparently monoglandular deficiency benefit more by mixed hormone treatment than by the administration of the extract from a single isolated unit of the endocrinous gland system. It is now recognised that normal metabolism depends upon the hormone balance being maintained, and that the functions of the endocrinic organs are plural rather than singular. The administration of gland substances must not be regarded from the narrow standpoint of replacing a deficient secretion, but rather as stimulating particular organs to greater activity for a longer or shorter time. "Polyglandin" enhances muscular, mental and nervous activity, and is a general stimulant to the cardio-vascular system.

"BYNOL"

To maintain body weight
and generally to promote
nutrition in Incipient
Phthisis & Wasting Disease

"Bynol" is a combination of Cod-Liver Oil and Malt Extract, having exceptional nutritive power. The Oil used in its manufacture is a pure product, in the preparation of which Messrs. Allen & Hanburys have been directly engaged for over half a century at Lofoten and Søndmør, Norway. Medical reports show that it is one of the best weapons for arresting loss of weight and increasing capacity for assimilation.

ALLEN & LONDON PARIS DURBAN	HANBURY'S LTD TORONTO SYDNEY SHANGHAI
--------------------------------------	--

Five seconds by the Watch

PHYSICIANS do well to be particular as to the character of the hypodermic tablets they use. A tablet that dissolves promptly and thoroughly is essential. Mere disintegration will not suffice. Many hypodermic tablets "go to pieces" in water—fine, undissolved particles settling to the bottom. Such tablets are worthless in an emergency.

PARKE, DAVIS & Co.'s HYPODERMIC TABLETS

dissolve freely and fully, forming a clear solution, without residue. *Test one by the watch!* Drop the tablet into a syringe partly filled with lukewarm water. Shake vigorously. In five seconds (or less) it will have dissolved completely. *Try it!*

PARKE, DAVIS & Co.'s HYPODERMIC TABLETS are made from *standardised drugs* only, by a process which ensures absolute accuracy of dosage and the exclusion of impurities and germ infection.

A Selection from the list of Parke, Davis & Co.'s Hypodermic Tablets.

Aconitine (alkaloid), gr. 1-120.
Adrenalin, gr. 1-200 and 1-65.
Adrenalin and Benzamine (Eucaine).
Adrenalin and Cocaine.
Apomorphine Hydrochloride, gr. 1-20 and 1-10.
Apomorphine and Strychnine.
Arecoline Hydrobromide, gr. 1-100.
Atropine (alkaloid), gr. 1-150.
Atropine Sulphate, gr. 1-200, 1-150, 1-120, 1-100, 1-60 and 1-50.
Atropine and Strychnine.
Benzamine (Eucaine) Hydrochloride, gr. 1-4.
Caffeine, gr. 1-2.
Cocaine Hydrochloride, gr. 1-8, 1-6, 1-4 and 1-2.
Codeine, gr. 1-8.
Codeine Phosphate, gr. 1-4 and 1-2.
Coniine Hydrobromide, gr. 1-8.
Corrosive Sublimite, gr. 1-100.

Diamorphine (Heroin) Hydrochloride, gr. 1-21, 1-12, 1-6 and 1-4.
Digitalone, gr. 1-10, 1-2 and 1.
Emetine Hydrochloride, gr. 1-6, 1-3, 1-2 and 1.
Ergotinine Citrate, gr. 1-100.
Hyoscine (Scopolamine) Hydrobromide, gr. 1-450, 1-200, 1-150 and 1-100.
Hyoscine and Morphine.
Hyoscine Compound (Hyoscine, Atropine and Morphine).
Hyoscyamine (alkaloid), gr. 1-100.
Local Anaesthetic (Dental) (Cocaine, Morphine and Atropine).
Morphine Hydrochloride, gr. 1-8, 1-4 and 1-2.
Morphine Meconate, gr. 1-4 and 1-3.
Morphine Sulphate, gr. 1-12, 1-8, 1-6, 1-5, 1-4, 1-3, 3-8 and 1-2.
Morphine Tartrate, gr. 1-4.
Morphine and Atropine (fifteen different combinations).

Morphine and Strychnine.
Nitroglycerin (Trinitrin), gr. 1-200 and 1-100.
Nitroglycerin and Strychnine.
Physostigmine Sulphate, gr. 1-100.
Picrotoxin, gr. 1-50.
Pilocarpine Hydrochloride, gr. 1-8 and 1-6.
Pilocarpine Nitrate, gr. 1-4 and 1-3.
Quinine Acid Hydrochloride, gr. 5.
Quinine and Urea Hydrochloride, gr. 7-10 and 2.
Scopolamine Hydrobromide, see Hyoscine.
Scopolamine and Morphine.
Sodium Chloride, Pure, gr. 1-7.
Sparteine Sulphate, gr. 1-30, 1-10 and 1-4.
Strychnine Formate, gr. 1-60.
Strychnine Hydrochloride, gr. 1-60.
Strychnine Nitrate, gr. 1-100, 1-60, 1-40 and 1-20.
Strychnine Sulphate, gr. 1-150, 1-100, 1-60, 1-50, 1-40, 1-32 and 1-30.

For formulae of the compound tablets, also prices and packages, see price list.

PARKE, DAVIS & Co. LONDON W.

Rich
in
Diastase.

"MALTINE"

Rich in
Phosphates
and Proteids.

Professor CHITTENDEN (Yale University)
reports:—

"The results demonstrate conclusively the far greater diastasic value of your preparation, and enable me to state, without any qualification whatever, that 'MALTINE' far exceeds in diastasic power any of the preparations of malt which I have examined."

THE LANCET says:—

"'MALTINE' exhibits in an eminent degree the starch-dissolving power of diastase; in fact, a teaspoonful is capable of converting instantaneously a surprising amount of stiff starch paste into a thin limpid liquid."

"MALTINE" is readily distinguished from other extracts of malt by its agreeable flavour, convenient consistence, and attractive colour. Its diastasic strength, richness in reconstructive constituents, and easy assimilability are the facts which explain its use by medical men.

INDICATIONS:

- (1) As a nutrient in feeble nutrition and wasting disease.
- (2) As a starch digestant to aid feeble amylaceous digestion.
- (3) In fever and milk diets, to supplement nutrition and to prevent coarset curdling.
- (4) In Infant Feeding, to humanize cow's milk.
- (5) As a vehicle and emulsifying agent.
- (6) As a natural counteractant to constipation in infants and children.
- (7) As a galactagogue.

"MALTINE" with COD LIVER OIL.

The "BRITISH MEDICAL JOURNAL" states:
"Apart from its own dietetic value, 'MALTINE,' when combined with Cod Liver Oil, certainly enables the latter to be taken by persons who neither swallow nor assimilate it in any other form."

"Maltine" with Cod Liver Oil is Absolutely Palatable, and contains a satisfactory proportion—30 per cent. by volume—of Cod Liver Oil, is easily digested and possesses a high Food Value.

"MALTINE" WITH CREOSOTE.

Each Fluid Ounce contains Pure Beechwood Creosote 4 minims.

"MALTINE" is a very useful vehicle for the administration of this pungent and acrid drug, its Palatability making it an admirable corrective, while its beneficial influence on nutrition and digestion supports the action of the Creosote.

"MALTINE" WITH IRON.

Each Fluid Ounce contains—

IRON PYROPHOSPHATE ... 8 grains.

This is a particularly bland and assimilable preparation of Iron, in which the astringency of the ferruginous salt is counteracted by the slightly laxative action of the "MALTINE" base, which stimulates nutrition, aids digestion, and furnishes the blood with immediately available proteids and other food elements.

The word "MALTINE" is our Trade Mark. In prescribing kindly specify "MALTINE COMPANY."

THE MALTINE MANUFACTURING COMPANY, Limited,
183, ACTON VALE, LONDON, W. 3,

Will be pleased to send Specimens Free of Charge to Medical Men.

LAMP DEvised AND ONCE USED BY THE EARLIEST PIONEERS OF ARTIFICIAL LIGHTING.—

How the Magdalenian cave artists worked in remote galleries and recesses into which the light of day never penetrated

was for a time one of the mysteries which made it difficult to believe that the paintings there discovered were their work. The finding of the primitive lamp here reproduced—with several other specimens later—led to the solution of the problem. It consists of a large hollow pebble of fine limestone. When discovered it still contained traces of carbonaceous

matter which, in the opinion of a distinguished analyst, had resulted from the combustion of animal fat. This fat would provide the oil, and it is considered that, like the Eskimos (one of whose lamps is here reproduced on the right for comparison), the Magdalenians would use a piece of moss for the wick. Such a lamp, carefully kept, would give off very little smoke, and experiment has proved that any trace of smoke left upon the walls would soon fade off, this would satisfactorily explain away the objection that no traces of smoke are found. The base of the lamp is engraved with the head and horns of an ibex, which resembles one engraved upon a wall of the cave in which it was found.

THE TENTH LONDON MEDICAL EXHIBITION

Organised by the Management of the Exhibitions of the 17th International Congress of Medicine, 1913
and the Clinical Congress of Surgeons, 1914

THE CENTRAL HALL

WESTMINSTER, S.W.

Monday · Tuesday · Wednesday · Thursday and Friday,

OCTOBER 4, 5, 6, 7 and 8 · 1920

From 12 noon till 6.30 p.m. daily.

IN 1919 the Exhibition was held in the Central Hall and proved, in view of the large number of the profession who visited it, to be greatly appreciated. The scope of the Exhibition has this year been very considerably enlarged, more accommodation has been provided, and the display of the latest in the medical, hygienic, dietetic, surgical and dental sections will be found of more than usual interest.

The attendance is strictly confined to the Profession, and the public are not admitted. Last year the Exhibition was visited by several thousand Doctors.

There is a handsome Reception Room, where Light Refreshments are provided and a well known orchestra will perform each day.

Invitation Cards will be sent to every member of the Profession residing within a 50 mile radius of the Hall. Those in the Provinces who do not receive cards, desiring to visit the Exhibition, can obtain same on application to The Secretary, 194-200, Bishopsgate, London, E.C., or at the Box Office during the Exhibition week.

PRESS OPINIONS *of the* 1919 EXHIBITION.

The "Lancet."

"After a lapse of six years the ninth London Medical Exhibition was opened at the Central Hall, Westminster on October 6th, remaining open until to-day (Friday, October 10th). Former exhibitions organised and conducted under the same auspices, were held in the Horticultural Hall, Vincent Square. The drug instrument, and book trades were well represented at the exhibition, especially when there are taken into consideration the difficulties of transport and the general dislocation of business due to the recent strike. The exhibition proved of particular interest in showing the numerous and important advances made in this country, chiefly in the manufacture of chemical and pharmaceutical products and antiseptics during the period of the war. Preparations were to be found in good number, demonstrating agreeably how British manufacturers have risen to the occasion and have now established their laboratories and factories as reliable and adequate sources of supply of many products hitherto exclusively obtained from abroad. The arsenical synthetics, aceto-salicylic acid, peptone for bacteriological work, and drugs in colloidal state, may well be described as vindications of British powers of research and application. The demonstration served to show also how professional in character were the products, for the organisers have always made a point of keeping the exhibition exclusive to the medical visitor. Medical men found themselves able to spend a good deal of time in making a serious

review of the exhibits, for the exhibition proved a real demonstrative centre of new things in medicine and in surgery."

"The Times."

"The ninth London Medical Exhibition was opened yesterday at the Central Hall, Westminster. As the first of these exhibitions to take place since the war, it excited a great deal of interest. All the large British producing firms have stalls in the exhibition, and the advances made during the war, in both surgery and medicine, are illustrated. In addition a large number of new products are on view."

"The Daily Telegraph."

"The great war has done much to emancipate humanity, British and other, from dependence upon Germany. Two conclusions the visitor to the London Medical Exhibition, which is open this week at the Central Hall, Westminster, will inevitably bring away with him. One is that the average Englishman has been sadly lacking in acknowledging the debt that he owes to scientists of his own nationality. The second is that there is little for which we need now lean upon the German. There has been no Medical Exhibition since 1913. Six years' concentrated effort at beating the German at his own game, when necessity drove us to it, was bound to tell, and many of the stalls have their greatest display of preparations of British make throughout for which there is no longer any call to go abroad."

LEWIS'S PUBLICATIONS.

MIST. HEPATICA CONC. (HEWLETT'S)

COMPOSITION.—Ext. Cascaræ, Ext. Rhei, Jalapin, Podophyllin, Cocainæ Hydrochlor., 1-12th gr. in each fluid drachm.

THIS excellent compound, first introduced as a general aperient and cholagogue, has now become a popular remedy, and attention has very recently been called to the value of the mixture, by various authorities, in that class of cases spoken of as Chronic Bilioussness, in Catarrhal Jaundice, and in the Jaundice of simple Hepatic Torpor. In passive or habitual Congestion of the Liver, so frequently met with, it has been used with marked benefit.

In the treatment of acute or temporary constipation, frequently met with in the convalescence from acute disease, and in pregnancy, or in the constipation due to sedentary habits, to a deficiency of intestinal secretion and of peristalsis, the mixture can be prescribed with wonderful effect, positively curing cases that have resisted other remedies.

The Dose is from 10 to 60 minims, according to the age and condition of the patient. One drachm is a direct aperient and is not accompanied by griping or tenesmus.

Packed for Dispensing only in 10-oz., 22-oz., 40-oz., and 90-oz. Bottles.

Price in England, 12/6 per lb.

Please write: "Mist. Hepatica Conc. (HEWLETT'S)" to ensure obtaining this Preparation.

Alcresta Tablets of Ipecac in Amebic Dysentery and in Endamebic Pyorrhea

The oral administration of the ipecac alkaloids is proving more advantageous than the hypodermatic injection of emetine, especially in the treatment of endamebic carriers and in the prevention of relapse.

UNCOATED AND DISINTEGRATING—CAUSE NO NAUSEA

Each tablet contains the alkaloids (emetine and cephaeline) from ten grains of Ipecac, U. S. P., held in an adsorption compound with hydrated aluminum silicate. The tablets disintegrate but this adsorption compound passes through the acid contents of the stomach and releases the alkaloids only in the alkaline intestinal secretions—thus preventing gastric disturbances.

Ten or twenty tablets, representing one hundred or two hundred grains of ipecac, may be given in a day without vomiting or nausea.

Distributed through the Drug and Dental Trades in bottles containing 40 and 500 tablets. Further information on request.

INDIANAPOLIS, U. S. A.

VITAMOGEN represents a highly Concentrated Food, and contains Free Vitamines in a natural and unchanged condition.

VITAMOGEN has been found invaluable in Cases of Depression following INFLUENZA.

VITAMINES.

"The **Vitamines** are bodies which, until recently, have been little known and less understood. Even now our appreciation of their behaviour under certain circumstances in the impure state is far in excess of our knowledge of their true character and actual essential composition.

Physically, chemically, and structurally they are delicate substances, since heating above a relatively low temperature irretrievably destroys their activity (sterilising).

Deficiency diseases caused by the absence of **Vitamines** yield rapidly to a course of **Vitamine**-rich diet. Such a diet will not only prevent the occurrence of **Rickets** and **Scurvy**—and, to go further, **Beri-Beri** and **Pellagra**—but is the best, in fact the only, treatment to arrest the progress and cure these conditions, except in so far as any definite anatomical deformities of the bony parts have taken place. These are, of course, only amenable to orthopædic and surgical treatment. It is therefore essential to prevent the occurrence of any crippling malformations by promptly assuring a **Vitamine**-rich pabulum for the organism.

When we try to define the exact composition of **Vitamines** we are unable to do so at our present state of knowledge. We can extract the active principle from certain foods naturally rich in **Vitamines**, but so elusive are the essential **Vitamine** principles that they have not yet been isolated. An extract of this sort, presenting all

the active and valuable properties of the **Vitamine** principles in a condensed form, is **VITAMOGEN**.

By its addition, any food that is palatable and assimilable can be made nutritious and powerfully reparative to tissue waste. The **Vitamines** presumably act, in part at any rate, by hormonically activating the internal secretions of the essential auxiliary digestive organs."

Vitamogen is useful in any form of **Nervous Disease**—**Neurasthenia**—**Shell Shock**—**Hysteria**—**Anæmia**—**Nervous Dyspepsia**—and all **Wasting Diseases**—**INFLUENZA**—and for its great Tonic-effect in convalescence after severe illness, owing to its properties of aiding the body to form fresh tissues to replace those which have been wasted, **Sleeplessness**—**Malnutrition** and the effects of **overwork** and **Nervous break-down**. It is indicated where a **Tendency to Rickets** or **Dental Caries** is manifested.

Vitamogen is packed in two sizes—2/9 and 5/9, or in bulk for Hospitals. Literature on the Vitamines will be sent upon application to VITAMOGEN, Ltd., 24/26, Holborn, London, E.C. 1.

THE LANCET ANALYSIS.

Moisture, 7.00; mineral matter, 7.50 (equal to 2.50 phosphoric acid); protein, 24.96 per cent.; sugar, 20.83; starch, 26.25; fat, 1.61; cellulose or fibre, 11.95. The preparation is largely soluble in cold water, the total soluble matters amounting to 62.80 per cent. **VITAMOGEN** also contains, as will be seen from the analysis, a rich proportion of phosphoric acid.

Fellows' Syrupus Hypophosphitum

A concentrated mineral pabulum, possessing unrivalled therapeutic properties in all Wasting Diseases, which have been termed "Demineralizations" by modern clinicians.

Supplies the organism with those indispensable mineral elements:
Manganese Potassium Sodium Calcium Iron
 together with the dynamic action of quinine and strychnine.

"THE STANDARD TONIC."

HORLICK'S MALTED MILK

The Ideal Food from Infancy to Age.

A thoroughly pure full-cream milk, enriched with the soluble nutritive extracts of choice malted barley and wheat-flour, containing no unaltered starch and no cane sugar.

Being rich in growth-promoting and other strength-giving Vitamines it is pre-eminently suitable for infants from birth, whilst forming an ideal and reliable nutrient for all ages.

READY IN A MOMENT. NO ADDED MILK OR COOKING REQUIRED.

Used extensively and successfully during the war by all the Expeditionary Forces.

In Sterilized Glass Bottles of all Chemists and Stores, 2/-, 3/6 and 15/-

Always specify "Horlick's Malted Milk."

Samples will be forwarded free and postage prepaid to Members of the Medical Profession on application to
HORLICK'S MALTED MILK CO., SLOUGH, BUCKS, ENGLAND.

THE BURBERRY

The Super-Weatherproof

REPRESENTS the most economical and distinguished form of protection in out-door Dress.

THE BURBERRY, by its efficient resistance to rain and cold winds, ensures comfort and security under conditions entailing prolonged exposure to chill and damp.

THE BURBERRY, by faultless natural ventilation, entirely avoids the vitiated heat of macintosh or rubber-lined coats.

THE BURBERRY is airy and gives a splendid sense of freedom, whilst its hygienic warmth in chilly weather proves invaluable for maintaining health and comfort.

Patterns, Prices, and Catalogue sent on application.

BURBERRYS' CLEANING WORKS.

Men's and Women's Dress Cleaned by the most up-to-date processes. Weatherproof garments reproofed. Moderate charges. Prices sent on request.

BURBERRYS' BASINGSTOKE HOUSE treats direct commissions from Doctors as approval orders—i.e., replaces with its own cheque returned non-approved garment.

KEROL

KEROL combines all the properties which go to the making of an ideal preparation.

It has been shown to be practically non-toxic, non-irritant and non-corrosive—a combination of properties which make it the one preparation which can be used with perfect confidence wherever the use of either a disinfectant or antiseptic is indicated. It is of high and definite germicidal value and is perfectly homogeneous

KEROL is highly recommended by Bacteriologists and by prominent members of the Medical Profession.

KEROL CAPSULES

INTESTINAL. These are of great value where intestinal antiseptics is indicated. In a comparatively short space of time the coli content of the intestine is reduced by over 99 per cent. They are non-irritant and perfectly safe.

STOMACHIC. For use in cases of stomach fermentation and other gastric troubles, and are of great value in reducing the number of malign organisms prior to administration of treatment with lactic ferments, i.e., sour milk, etc.

City of Leeds.—Appointment of an Additional ASSISTANT MEDICAL OFFICER for Maternity and Child Welfare. Applications are invited from qualified and registered Medical Practitioners, Male or Female, for the post of Assistant Medical Officer for Maternity and Child Welfare. Applicants must have had experience in a general hospital subsequent to qualifying, and also experience in the treatment of children's diseases, either in a sick children's hospital or in wards of a general hospital set apart for children. Experience in the treatment of diseases of women and the possession of the D.P.H. would be considered additional qualifications. The salary offered is £500 per annum.

Intending candidates should apply in the first case to the Medical Officer of Health, 12, Market-buildings, Vicar-lane, Leeds, for particulars as to the duties of the appointment and for form of application.

Applications, together with copies of three recent testimonials, endorsed "Maternity and Child Welfare Officer," should be delivered to the undersigned not later than Monday, October 4th. Leeds, 11th September, 1920. ROBERT E. FOX, Town Clerk.

Pontypridd Urban District Council.—The Pontypridd Urban District Council invite applications from fully qualified Medical Women for the position of ASSISTANT MEDICAL OFFICER, whose principal duties will be the Medical Inspection of School Children and the work of Maternity and Child Welfare, together with other duties which may be assigned to her from time to time by the Medical Officer of Health, at a commencing salary of £550 per annum, rising by annual increments of £50 to £650 per annum.

The lady appointed will be required to devote the whole of her time to the duties of the office and will not be allowed to engage in private practice, also to act under the general direction of the Medical Officer of Health.

Candidates should be competent to perform the simpler refraction work and to prescribe spectacles for School Children, the more difficult cases being referred to a Specialist. Preference will be given to candidates who have had previous experience in School and Maternity Work, and such experience in the work of Maternity and Child Welfare Centres will be considered in assessing the initial salary.

The appointment will be terminable by three calendar months' notice on either side.

Forms of application may be obtained from: The Medical Officer of Health, Municipal Buildings, Pontypridd, and should reach the undersigned not later than 30th September, 1920, endorsed "Assistant Medical Officer of Health." H. LEONARD PORCHER, Clerk to the Council. Municipal Buildings, Pontypridd, Sept. 14th, 1920.

Worcestershire County Council.—SCHOOL OCULIST.—The above-named Council are about to appoint a School Oculist, who must be specially experienced in Eye Diseases and their Treatment, and competent to undertake the correction of errors of refraction.

The duties will be to examine and, where necessary, to treat the eyes of children in the County Schools.

Applicants, either male or female, must be registered Medical Practitioners of suitable experience and qualifications, and be between twenty-five and forty-five years of age. The person appointed will be required to reside in the district assigned to him or her by the County Council, to devote the whole of his or her time to the work, and will be subject to the directions of the County Medical Officer.

The salary will be £550 per annum, rising to £600 by two equal annual instalments, in addition to allowances for travelling and personal expenses.

Experience in motor driving is desirable. The engagement will be subject to three months' notice on either side.

Applications (on forms to be obtained from the County Medical Officer), accompanied by not more than three recent testimonials, must be received by 12 noon on Tuesday, the 5th October, 1920, addressed to the County Medical Officer, 29, Foregate-street, Worcester, and endorsed "School Oculist."

Canvassing disqualifies, and neither the names of the County Council nor of the Committee will be supplied.

C. H. BIRD, Clerk of the County Council. Shirehall, Worcester, 14th September, 1920.

Applications, stating age, qualifications, with copies of testimonials, to be sent in on or before Saturday, October 9th, 1920, addressed Chairman, House Committee.

City of Leeds.

LEEDS CITY HOSPITALS, SEACROFT (500 Beds).

An **ASSISTANT MEDICAL OFFICER**, Male or Female, who should be unmarried, is required in these Hospitals about the middle of October. The officer will be required to act under the directions of the Medical Superintendent, and to have some knowledge of ordinary bacteriological methods, and should also provide own bacteriological microscope, with 1-12th oil immersion lens.

The diseases ordinarily under treatment are those scheduled in the Infectious Diseases Notification Act.

The salary is £300 per annum, with board, lodging, washing, and attendance.

Application, with copies of recent testimonials, must be sent to the Town Clerk, Leeds, not later than Saturday, 2nd October, 18th September, 1920.

Wilts County Council.—Appointment

of **ASSISTANT COUNTY MEDICAL OFFICER OF HEALTH** and **ASSISTANT SCHOOL MEDICAL INSPECTOR**.—The Wilts County Council invite applications for the appointment of an Assistant County Medical Officer of Health and Assistant School Medical Inspector. Applicants must be fully qualified Medical Practitioners and must hold a Diploma in Public Health or an equivalent qualification. The commencing salary will be £600 per annum. The officer appointed will be required to devote his whole time to the duties of the office, and to act under the direction and control of the County Medical Officer of Health, who is also School Medical Officer. The duties of the post will be chiefly concerned with the School Medical Service, but in addition a certain amount of the officer's time will be devoted to the Public Health work of the County. The appointment will be determinable by three months' notice on either side.

Applications on form to be obtained from the undersigned, together with not more than three recent testimonials, and enclosed in envelope marked "Assistant Medical Officer," to be lodged with the undersigned not later than Saturday, 9th day of October, 1920.

Canvassing, either directly or indirectly, is strictly prohibited, and will be regarded as disqualification.

W. L. BOWN, Clerk of the County Council.
County Offices, Trowbridge, September, 1920.

Queen's Hospital, Birmingham.—

Applications are invited for the following Resident Appointments:

HOUSE PHYSICIAN to serve under Dr. Stanley for six months ended March 31st, 1921.

HOUSE PHYSICIAN to serve under Dr. Emanuel for six months ended March 31st, 1921.

HOUSE SURGEON to serve under Mr. Leedham-Green for six months ended March 31st, 1921.

HOUSE SURGEON to serve under Mr. Billington for six months ended March 31st, 1921.

HOUSE SURGEON to serve under Mr. Nuthall for three months ended December 31st, 1920.

OBSTETRIC and OPTHALMIC HOUSE SURGEON for six months ended March 31st, 1921.

CASUALTY HOUSE SURGEON for six months ended March 31st, 1921.

Salary in each case at the rate of £90 per annum, together with board, apartments, and laundry.

Candidates, who must be fully qualified and registered, to send in their applications, together with certificate of registration, to the undersigned.

ELLIS C. SMITH, Secretary and General Superintendent.

Birmingham Union.

MONYHULL COLONY FOR EPILEPTICS & FEEBLE-MINDED.
RESIDENT MEDICAL OFFICER.

The Guardians invite applications from duly qualified Medical Men for the appointment of Resident Medical Officer at Monyhull Colony. Accommodation—500 patients on the Adult Section, and 350 patients on the Children's Section, which is certified by the Board of Education as a Residential School under the Elementary Education (Defective and Epileptic Children) Acts. Included in the above numbers are 140 patients certified under the Mental Deficiency Act, 1913.

Candidates must not be more than forty-five years of age, and will be required to undertake Research work for the purpose of medical investigation into the causes of epilepsy and mental deficiency.

The person appointed will be required to devote his whole time to his official duties (a schedule of which will on application be forwarded to any prospective candidate), and the appointment will be subject to the provisions of the Poor Law Officers' Superannuation Act, 1896.

The remuneration will be £700 per annum (inclusive of War Bonus), and residential emoluments will be provided, consisting of a furnished house or apartments, board, laundry, and a servant, such emoluments being valued at £200 per annum for Superannuation purposes.

Applications, stating age, qualifications, and experience, and accompanied by copies of not more than three recent testimonials, must reach me not later than Thursday, 7th October, 1920. Canvassing strictly prohibited.

JAMES CURTIS, Clerk to the Guardians.
Union Offices, Edmund-street, Birmingham, 22nd September, 1920.

Valentine's Meat-Juice

For Quieting the Irritable Stomach in Pregnancy, for Rapidly Restoring the Vital Forces in Hemorrhage, for Sustaining and Strengthening in Long and Exhausting Labor, Valentine's Meat-Juice is Extensively employed in

Obstetrical Practice

Dr. M. DeCristoforis, Prof. Lecturer on Midwifery and Gynaecology, Milan, Italy: "The preparation, VALENTINE'S MEAT-JUICE, has been successfully used by me in a serious case of acute puerperal hemorrhage. The patient could take no food or drink. VALENTINE'S MEAT-JUICE was completely retained and restored very promptly the strength and the cardiac impulsion."

Dr. E. Duloir, Physician Accoucheur to the International Hospital, Paris, France: "A young accouchée, in a very weak condition and suffering from stomach trouble, could retain no food, but was able to assimilate VALENTINE'S MEAT-JUICE given at first in small doses. An improvement was quickly visible, the patient recovered her strength and is today in good health."

For Sale by European and American Chemists and Druggists.

VALENTINE'S MEAT-JUICE COMPANY,

D 135

RICHMOND, VIRGINIA, U. S. A.

Quotations from Doctors: No. 5

"My patient, a dentist, scalded from the bursting of a vulcanising flask, was in great agony. I hastily applied

Antiphlogistine

the only thing convenient at the moment. Intended it for a temporary dressing until the ordinary substances used in such cases could be obtained. The relief was so great and instantaneous that the dressing was allowed to remain until a later visit, when upon its removal twelve hours after, the skin was found to be white and free from inflammation. Another application was allowed to remain for twenty-four hours. When discontinued there were no blisters, no redness, nor any evidence of the burn, excepting the eyelids and around the eyes where the Antiphlogistine had not been applied. Have used this preparation again and again in burns of the first degree with invariably good results."
